¹It should be noted that the average values reported in this survey are far below those reported in response to a similar question in the 1977 *QES*, as well as in a data set I collected in 1986 (see my forthcoming article). Possible reasons for these relatively low values include that all values were reported by the head of household for both the head and spouse, which may lead to

TABLE 1—AVERAGE VALUES OF TIME SPENT
PER WEEK ON HOUSEWORK
BY MARKET WAGE EARNERS IN SAMPLE

	Mean ^a	Sample Size
Married Men:		
Children	8.96 (7.58)	1217
No Children	7.58 (6.29)	532
Married Women:		
Children	19.42 (10.61)	1031
No Children	15.16 (8.21)	587
Not-Married Men:		
Children	10.43 (7.50)	70
No Children	7.73 (5.75)	395
Not-Married Women:		
Children	13.98 (8.32)	300
No Children	10.06 (7.36)	386

^aStandard deviations are shown in parentheses.

Most noteworthy are the dramatic differences in housework time by gender. The time spent on housework by women exceeds that of their male counterpart in every category, statistically significant at the .01 level or better in every case. Married women with children average nearly 20 hours per week on housework, more than double that of married men with children. Married women without children average 15 hours of housework per week, which is 7.58 hours more per week than married men without children. Note that the time spent on housework for married women is usually reported by their husbands, and may be an underestimate of the true value.

Wages and time spent on housework are determined jointly, with higher wages mak-

ing substitutes for nonmarket work more affordable. This suggests that the appropriate procedure is to estimate a two-equation wage-housework system. Accordingly, Table 2 presents the results of this estimation, where the estimation procedure is two-stage least squares (2SLS).

The wage equation takes the standard human capital specification, augmented by hours of time spent on housework. The log of hourly wage is regressed on hours per week spent on housework, years of education, the log of years of tenure with employer, and years of full-time work experience and its square. In addition, the regression includes dummy variables equal to one if the worker is white, handicapped, married, in a job covered by a union contract, in a white-collar job, is employed full time, or resides in the South. The inverse Mill's ratio, calculated from the full sample of workers and nonworkers, is also included in the wage equation to correct for possible selection bias that may occur since we observe only wages of individuals whose market wage exceeds their reservation wage.²

One determinant of time spent on housework is the market wage rate, since higher market wages make substitutes for own housework more affordable. In addition, time spent on housework will be affected by a variety of individual and household characteristics, as well as by cultural differences and individual attitudes. The household characteristics include number of children (in four different age ranges), number of rooms in the home, and dummy variables equal to one if the individual is married and if the individual lives in a house (rather than an apartment or trailer). Differences in attitudes or cultural differences may be accounted for by race, education, age, and

underreporting of wives' time spent on housework. In addition, unlike the QES and my survey that requested information on time spent daily on household chores including yard work, repairs, and shopping, the PSID question only requested a summary measure for the week and did not prompt for household chores other than cooking and cleaning, again leading to the likelihood that the time spent on housework is underreported.

²The inverse Mill's ratio was estimated from a probit equation (not reported) that estimated the probability of labor force participation from age, race, handicapped status, marital status, number of children under age 6, number of children between ages 6 and 18, a dummy variable indicating that there were no children under age 18, years of education, and the wage rate for unskilled workers in the county of residence.

^aStandard errors are shown in parentheses.

residence in the South. Other family income (net of the individual's own labor income) is included to indicate the household's ability to afford substitutes for nonmarket work. The county wage rate for unskilled labor proxies for the cost of substitutes such as paid housekeepers.

The results of the simultaneous estimation of the wage-housework system are presented in Table 2. The wage equation conforms to standard estimates of wage equations. Wages rise with tenure and years of work experience at decreasing rates, more educated workers tend to earn higher wages, as do union, white-collar, full-time, and white workers, and workers not located in the South.

The time spent on housework by both men and women is primarily affected by the presence of children and by the number of rooms in the home. White women and married women spend more time on housework, while white men and men in larger families spend less time on housework. The negative effect of family size on housework performed by men, after controlling for the number and ages of children, may be due to the presence of other adults (for example, parents) that can help with housework. Other family income does not have a significant effect on time spent on housework for either men or women.

Most noteworthy is the significantly negative effect of housework on wages, and of wages on housework, for the sample of women. Each extra hour of housework reduces women's hourly wages by an average of .6 percent, while each extra dollar per hour in wages earned by women reduces her time spent on housework by about 2.5 hours. Surprisingly, men's wages are positively and significantly related to time spent on housework, while time spent by men on housework is not affected by their wage.

II. Discussion

The results indicate that women's wages, but not men's, are reduced by time spent on housework. Further, the time spent by women on housework is inversely related to her own earnings, but is not affected by the household's other income. Men's time on

housework is unaffected by their wage or by other family income.

The basis for the inverse relation between women's wages and time spent on housework may be due to a number of related factors. These include the possible direct effect of housework on market effort and the possibility that household roles affect demand for working conditions and thereby wages as a compensating differential. A further possibility is that women who have demonstrated that family life is a priority are placed on a so-called "mommy track" with reduced work responsibilities and promotion prospects.

Housework may have a direct effect on market productivity, after controlling for any effects that anticipated household responsibilities have on human capital acquisition. The direct effect may be caused by a reduction in the amount of effort available for market work. This result is consistent with my earlier research, using two other data sets, that indicates that housework has a negative effect on women's wages (see my 1985 and forthcoming articles). Yet time spent on housework apparently has a positive effect on the wages of men.

Since women spend more time on housework than men, any negative effect of housework on wages may begin at a point beyond the average amount of time spent on housework by men. Further, it is more likely that the timing of household chores is different for men and women. Women are more likely to take responsibility for chores that have a time element associated with them, such as cooking a meal or arranging doctors' appointments for children. Because such activities make schedules less flexible, market work is more likely to be disrupted for women than men. For instance, women may be less likely to work late than men, and more likely to take time off work to make and meet family-related appointments.

To the extent that housework interferes with women's market work because of scheduling and physical and mental effort, we would expect to see women in jobs with characteristics that reflect these different requirements. If these job characteristics warrant lower pay as a compensating dif-

ferential for favorable job conditions, then the negative effect of housework on wages may be spurious, and instead due to the correlation of housework with unobserved working conditions that warrant lower wages as a compensating differential. This hypothesis cannot be tested using the *PSID* data set, but I have tested this theory using data I collected, with the results presented in my forthcoming article. I find that although men and women are in jobs with very different characteristics, time allocated to household responsibilities has an independent negative effect on women's wages, controlling for differences in working conditions and human capital.

A second hypothesis regarding the manner in which housework reduces wages may be due to the indirect effect referred to as the mommy track. The notion of a mommy track suggests that family responsibilities and careers are fundamentally incompatible, and the expectations on the job for women should accordingly be scaled down. Women that have demonstrated that they are taking on household chores may be de facto placing themselves on a slower track with respect to promotions. Thus lower wages accompanying greater household responsibilities may be caused by women being promoted at different rates than men with otherwise similar human capital characteristics.

However, despite the popular press notion that women are victims of men and are forced to do housework to the detriment of their careers, it is worth noting that even childless unmarried women spend more time on housework than their male counterpart. This suggests that at least some of the extra time on housework spent by women is due to differences in tastes.

Gender Differences in Labor Market Effects of Alcoholism

By JOHN MULLAHY AND JODY L. SINDELAR*

Little is known about the role of specific health problems in affecting labor market productivity. Even less is known about gender differences in the labor market effects of such health problems. Current knowledge of health effects is based largely on samples composed exclusively of men, a common practice in both economics and health research. In the latter case, even a congressional mandate to incorporate females in study samples is reputed to have had little effect (Patricia Schroeder, 1990).

In this study, we attempt to determine the structure of gender differences in labor market responses to alcoholism. We use a relatively new data source that allows such comparisons by gender in a large community-based sample. Previous studies have established that there are significant gender differences in labor market behavior. Differences in prevalence rates of alcoholism by gender are also well established. It is estimated that 3 percent of females are currently suffering from alcoholism and twice that many have exhibited symptoms at some time; for males the numbers are 10 and 20 percent, respectively. There is some medical evidence to indicate that physiologically, women and men respond differently to alcohol. For example, a recent study suggests that women have greater vulnerability to the acute and chronic health conditions associated with alcoholism (Mario Frezza et al., 1990).

I. Background

There are many debates surrounding alcoholism and alcohol consumption, ranging

from the effectiveness of treatment of alcoholism to the productivity effects of alcohol. There is even debate as to the sign of the effect of alcohol and alcoholism on the earnings of men. From Adam Smith, to Irving Fisher's denunciation of drinking as a detriment to productivity, to more recent studies, many have supported the idea that alcoholism or alcohol consumption has a negative effect on income and productivity. Yet others have found either insignificant effects (Lee Benham and Alexandra Benham, 1982) or even positive effects (Mark Berger and J. Paul Leigh, 1988). There is also a debate over whether alcoholism is a disease or a result of rational choices. At least in the medical literature, alcoholism is generally considered a "disease," "disorder," or "allergy."

Another cloudy area is the causal path by which alcoholism affects an individual's labor market outcomes. Early onset of alcoholism may retard educational achievement (see our 1989 and 1990b articles) and affect marital history. Current alcoholism could affect labor supply decisions (by changing the value of time at home vs. in the market), wage rates (by affecting occupational choice and reliability of the worker), nonwage income (by affecting marital status, spouse's labor supply decisions and/or transfer payments), and accumulated wealth (by influencing savings rates, past wage rates and labor supply, earned pension rights, etc.). Thus alcoholism could have direct effects on earnings as well as indirect ones. While we can specify neither the causal relationships nor their lifetime paths, it is important to keep these in mind when viewing and interpreting the data.

II. The Data

We use multiple site data from the Epidemiologic Catchment Area (ECA) survey. This set of surveys was designed to assess the prevalence of psychiatric problems (including alcoholism) by socioeconomic and

*Department of Economics, Trinity College, Hartford, CT 06106, and Resources for the Future; and Department of Epidemiology and Public Health, and Institution for Social and Policy Studies, Yale University, New Haven, CT 06510, respectively. Grant R01AA08394 from NIAAA supported this work. We thank Bernie Devlin for his programming assistance and Jean Mitchell for comments.

demographic characteristics in a community setting (see D. A. Reiger et al., 1984). Prior to the availability of the ECA surveys, there were no large samples assessing alcoholism and other disorders that contained professional measures of disorders. The ECA study comprised five sites. However, as one site gathered no information on income, we confine our analysis to data from Baltimore, MD, Durham, NC, Los Angeles, CA, and New Haven, CT.

We use as our definition of alcoholism whether the individual has ever met the criteria for alcohol dependence or abuse (see our 1990c paper for a discussion of the measurement of alcoholism). We refer to this as *ALCEVER*. We focus on *ALCEVER* as it is more likely to be exogenous to current behavior than is whether the person is currently manifesting symptoms. We treat *ALCEVER* as an exogenous variable because this is consistent with the disease perspective of alcoholism, and because it is econometrically necessary as there are no reasonable instrumental variables in the data set. This is also in keeping with the standard practice of treating health as an exogenous variable in labor market regressions.

To obtain an overview of gender differences, we compare the mean values of various socioeconomic characteristics of alcoholics to nonalcoholics for men and women separately. For both genders, nonalcoholics have higher educational attainment, are more likely to be working, are more likely to have white-collar jobs, and have higher incomes but are less likely to have transfer income.

Alcoholism appears to affect women somewhat differently than it affects men. For example, the percentage difference in household income by alcoholic status is bigger for women than for men. Further, alcoholic women are more likely than alcoholic men to never marry, have fewer children, and have more psychiatric disorders.

III. Life Cycle Dimensions to Alcoholism Problems

In previous work (1990c), we hypothesized that the labor market effects of alco-

holism would vary over the life cycle. That is, in the earlier ages, those suffering from alcoholism might either pay less attention to their schooling or drop out completely. In either case, young alcoholics may have higher wages due to more labor market experience and may also work more hours than their nonalcoholic counterparts. In the prime working ages, alcoholics would lose their lead in earnings and would have relatively lower wages as a consequence of their lower educational attainment, *ceteris paribus*. Yet, older alcoholics might tend to remain in the labor force longer than their nonalcoholic counterparts who have begun to withdraw from the labor market due to their greater accumulation of wealth and pension rights.

In work that used a sample of males from the New Haven site of the ECA survey (our 1990c paper), we found some evidence consistent with these hypotheses. Here, with a more comprehensive sample, we analyze how such relationships may differ by gender examining how alcoholism relates to work status (presently working full time), household income, and personal income. By way of a simple comparison of means, Table 1 provides some insights into these relationships by age groups. These comparisons are inherently not *ceteris paribus* comparisons; this issue we address below in Section IV.

In the three older age groups, the probability of labor market participation for both males and females is reduced substantially when individuals are alcoholic. This is in contrast to the youngest cohort where no negative effects are seen. As shown by the Household Income and Personal Income (displayed for workers only) panels of Table 1, there is little ambiguity about the relationship between alcoholism and income for the prime age groups 30–59. For both genders and for both household and personal income, alcoholism results in negative effects except for personal income of females ages 30–44.

Consistent with our earlier work with the New Haven sample, working alcoholic males in the youngest age category have somewhat greater income than nonalcoholics in the same age range, although this does not hold for females of the same age. Among work-

TABLE 1—SAMPLE MEANS BY AGE AND ALCOHOLISM STATUS: WORK STATUS; HOUSEHOLD INCOME; AND PERSONAL INCOME FOR WORKING FEMALES AND MALES

Ages	Females <i>ALCEVER</i>		Males <i>ALCEVER</i>	
	= 0	= 1	= 0	= 1
Work Status (Working = 1)				
18–29	.50	.50	.72	.75
30–44	.59	.48	.89	.79
45–59	.49	.26	.79	.66
60–64	.30	.24	.50	.37
Household Income (in \$1,000)				
18–29	22.0	18.6	22.8	23.9
30–44	24.7	20.8	28.7	25.6
45–59	23.1	22.8	30.1	27.3
60–64	16.7	21.1	28.7	21.9
Personal Income (in \$1,000)				
18–29	10.4	10.0	14.2	14.7
30–44	14.3	15.3	23.4	20.8
45–59	13.2	11.9	24.7	21.5
60–64	12.1	13.4	24.7	19.3

ing women, however, the older alcoholics (ages 60–64) have larger mean incomes than their nonalcoholic counterparts (although the sample size on which this comparison is based is small). A striking result revealed by these age-income profiles is that household income plummets for nonalcoholic but not for alcoholic working women in the oldest group. Consistent with this is the fact that personal income for alcoholic working women increases in moving to the oldest age group while it declines for nonalcoholic women.

Table 1 suggests, among other things, that the two middle-age groups for both sexes are relatively homogeneous with respect to the labor market effects of alcoholism, while both the youngest and the oldest group are somewhat different. We thus proceed to focus on the prime-aged working group (ages 30–59) on the premise that they and only they can be reasonably pooled together.

IV. Econometric Models

Given these relatively homogenous samples of prime-aged men and women, we attempt to address the *ceteris paribus* issue

raised above. That is, although we have shown that prime-aged alcoholics tend on average to work less and have lower incomes when working, it is not clear from the comparisons in Table 1 whether this is due to alcoholism per se, or rather to other characteristics of alcoholics.

To address this issue, we estimate several models of the probability of working, household income, and personal income, where income is measured in logs of interval mid-points. For the income equations, we estimate models for both the entire sample and also for the presently working subsample. Personal income, especially for workers, is closer to a measure of the individual's labor market productivity. However, when analyzing household income, one captures the possible effects of marital status and also of spouse's labor supply and earnings responses. Spouses may adjust their labor supply in response to a spouse's alcoholism for a variety of reasons, including the income effect and a change in the pleasantness vs. the productivity of time at home. The possibilities of alcoholism-related changes in the marital status and of assortative mating also complicate the issue.

The models are specified as functions of alcoholism as well as other more-or-less standard covariates that typically appear in earnings functions. Table 2 describes the variables in addition to *ALCEVER* that are used in the models.

The idea is to specify first a model in which the alcoholism variable is left to absorb the effects of the other human capital variables that are not included but that may be correlated with alcoholism. In a sense, these results mimic those in Table 1 except here we have adjustments for age, race, and the ECA survey site. This coefficient on alcoholism is an estimate of the total effect of alcoholism. Then we add variables that may be correlated with, and perhaps to some degree determined by, alcoholism. (Unfortunately, our data do not allow us to address satisfactorily the cause-effect issue.) In this latter case, the coefficient on alcoholism captures only part of the total effect, the rest of the effect occurs through other human capital components that vary with alcoholism. Thus there are two possible mea-

TABLE 2—REGRESSION COEFFICIENTS ON *ALCEVER*

	{-.09}	{-.001}	{-.11}	{-.03}

Note: Col. A. Controls for: geographic site, race, age, and age squared. B. Adds: education, education squared, number of children, marital status, transfer income, other household income (in the personal income equation only), and other disorder measures whose inclusion varies by gender: for females and males, anxiety, drug problems, and an aggregate of any other disorder; for males only, antisocial personality; and for females only, depression.

^aEstimated by logit. Figures in square brackets are $\hat{\beta}_j \hat{\pi}(1 - \hat{\pi})$, i.e., the "partial derivatives" of the predicted probabilities with respect to the dummy.

^bFigures in curly brackets are the estimated percent changes in income due to turning on *ALCEVER*, i.e., $\exp(\hat{\beta}_j) - 1$.

tures of effects of alcoholism. In one, the coefficient on alcoholism absorbs all of the effects (direct and indirect), while in the other, the coefficient estimates the partial effect holding other variables constant.

The regressions that include only the sparse set of covariates (cols. A in Table 2) provide an estimate of what we term the total effect of alcoholism on labor market

success. These results are striking and indicate that in what we feel to be a relatively homogeneous sample, alcoholics have dampened labor market success when compared with nonalcoholics.

For the logit models of presently working, the *ALCEVER* coefficients are negative and statistically significant for both genders. While the point estimate itself is larger for males, the partial derivative of the probability of working with respect to *ALCEVER* (displayed in brackets) is almost twice as large for females as for males. The effects are similarly negative and significant (except for personal income for females) for the log-income models (cols. A). The percentage reductions in income implied by the point estimates of the *ALCEVER* coefficient (displayed in curly brackets) indicate that these effects are sizable. We consider comparisons of household income for all individuals and personal income for workers only as the most meaningful comparisons; this is because the former will capture the effects of alcoholism on household structure and labor supply while the latter is more likely to capture individual productivity effects. These results indicate that the effects of alcoholism are greater on household income for women, but are similar by gender for personal income.

When we include the set of human capital variables omitted from the first estimates (cols. B), the coefficients on alcoholism are reduced in magnitude and significance for both sexes and for all measures of labor market success. This suggests a strong relationship between alcoholism and these other variables, and, therefore, supports the possibility of important indirect effects. In the context of omitted variable bias, this is hardly surprising. Note that the effects of alcoholism on labor market participation are still significant even when controlling for these other determinants, with the effect for females again estimated to be about twice that of males. However, for income, these effects generally become insignificant when moving to column B. Thus the effect of alcoholism is found to be stronger on labor force participation than it is on income, especially personal income.

V. Summary

Access to the multiple site ECA data allows the first large population-based inquiry into gender differences in the effects of alcoholism on labor force participation and earnings. In summary, we find that alcoholism typically has negative effects on both labor force participation and income for our sample. However, the effects vary across the life cycle and by gender. The significance depends on what variables one controls for and whether one is examining participation or income. The range of the results that we present provides relevant bounds of the magnitude of the effects of alcoholism on these prime-aged individuals. These results help to explain how studies could produce different estimates of the effects of alcoholism on income. The effect can depend on what variables one controls for, the age distribution of the sample, and whether one is examining income or participation.

Europe Post-1992: Internal and External Liberalization

By ALEXIS JACQUEMIN AND ANDRÉ SAPIR*

The gradual completion of the single European Community (EC) market is a process of internal liberalization that takes place within the framework of a worldwide dynamics of structural adjustment. At the *internal level*, the process is well on its way for at least two reasons. First, most of the regulations needed to remove the remaining physical, technical and fiscal barriers between member states have been adopted. Second, corporate strategies have largely anticipated the conditions of the post-1992 single market through various forms of restructuring, including a growing concentration on the main product lines, an extension of geographic coverage, and a multiplication of cooperative arrangements, mergers, and acquisitions. At the *external level*, foreign competitors supplying products for which demand is income elastic will benefit from the European income growth induced by market integration. They will also benefit from scale economies provided by a large integrated market in which they compete with EC firms on equal terms. It remains true that many nontariff barriers affect external policies for products and services, and that the dangers of an EC turning more inward cannot be excluded.

The paper argues that at the micro and macro level, a combined internal and external liberalization is necessary for the full achievement of the post-1992 gains. This requires transnational rules of the game sustaining extra- as well as intra-EC competition, and cooperative policies making compatible regionalism and multilateralism.

I. Internal and External Competition

Theoretical and empirical research suggest that import competition within European markets imposes a major constraint on domestic firms' price-cost margins. The program for the completion of the EC's internal market by 1992 is largely based on the effects expected from a reinforcement of such a constraint. The 1992 program requires the removal of barriers still affecting intra-EC trade, and hence the strengthening of European competition. According to the European Commission's assessment of the economic effects of this liberalization, the overall result will be a significant welfare gain. Given these expectations, the combination of internal and external liberalization may be a superior policy to internal liberalization alone if external liberalization also exerts an appreciable competitive impact.

Two recent studies shed light on this question. The first (our 1990 paper) investigates empirically the relative trade discipline of intra- and extra-EC imports on European industry performance. Our estimates reveal that only extra-EC imports exert a significant disciplinary effect on price-cost margins. A second study (by Damien Neven and Lars Röller, 1990) concludes that the elimination of intra-EC barriers should increase extra-EC imports more than intra-EC imports. Hence, there is evidence that the main competitive pressure, both actual and potential, comes from the rest of the world rather than from within the EC.

More specifically, the external impact of 1992 will be felt most in those sectors where the EC's competitive position has weakened most since the mid-1970's (see Sapir, 1989). Those sectors can be divided into two clearly

distinct categories. The first consists of industries that are characterized by a low or average level of R&D, and by slight or average economies of scale: shipbuilding, footwear, textiles, and clothing. Despite considerable external barriers, European producers have suffered appreciable market losses in these sectors, generally owing to the comparative advantage enjoyed by the developing countries. The second category consists of high-tech sectors characterized by relatively substantial economies of scale, important learning processes, and high sunk costs: telecommunications, electronics, and computers. In these sectors the weak performance of EC producers contrasts with the gains by United States and Japanese exporters.

In both these sector categories, important choices will have to be made in the run-up to 1992. In the case of the low- or average-technology sectors, steps must be taken to ensure that EC commercial policy is not used in place of a more effective structural adjustment policy. In the high-tech oligopolistic sectors, the public authorities will have to resist purely defensive reactions and calls for protection, and will have to ensure that policies designed to promote competitiveness and competition are put in place.

Competition policy is one of the most important guarantees for the internal and external liberalization of the Common Market. It is by no means certain that, post-1992, economic agents will accept the operation of competition. As experience following the lowering of tariff barriers has shown, the EC authorities may well be confronted with growing private and public strategies that seek to diminish or distort competition. The EC authorities must then ensure implementation of *credible rules* that are directly applicable to all, including third-country companies. The competition rules of the Treaty of Rome are already applicable to both public and private restrictions of competition and, in both cases, have been tightened. Concerning public restrictions, an example relevant for the external impact of 1992 is the increased transparency of state-

aid policy, required by the Commission and, when necessary, the recovery of aids granted illegally.

Concerning private restrictions, a central regulation about mergers and acquisitions was adopted in December 1989. This regulation sets up EC controls over community-wide, cross-border operations, and there is a mandatory prior notification of the planned mergers of this kind. One characteristic is also crucial for the external impact of 1992: for assessing whether a merger is or is not compatible with the Common Market, the only basis is its impact on effective competition, at the exclusion of cost savings or other offsetting efficiencies. This absence of an "efficiency defense" in the text of the regulation reduces sharply the dangers of mixing competition policy with industrial policy (see Jacquemin, 1990).

Ambiguity remains over the interactions between EC trade and competition policy. Compared to the rule-based competition policy (probably the most impersonal and the least discriminatory means of social control of an economy), trade policy allows much more discretionary power. According to Article 113 of the Treaty of Rome, "the common commercial policy shall be based on uniform principles," but the trade rules do not exclude the adoption by the Council of Ministers of anticompetitive protectionist measures. In fact, maintaining intra-EC competition is a much more accepted goal than safeguarding competition from outside.

More specifically, the pressures for not disrupting economic transactions between member states could lead to a difficult choice between the erosion of intra-EC free trade and the erosion of free trade with the rest of the world. One unhappy implication is that in several domains, not only trade and competition policy follow different roads, but also interact in a perverse way. While a free-trade policy is part of competition policy, the use of instruments such as antidumping duties and voluntary export restraints not only affects extra-EC trade but, through a feedback effect, mitigates competition within the EC. Some authors (for

example, Patrick Messerlin, 1990) argue that in fact European antidumping (allowed by Article VI of GATT) actions have a procartel and promerger propensity. Such actions increase the capacity to cartelize for firms unable to collude without some kind of public support; they also induce EC firms to merge with foreign firms operating in EC markets to the extent that EC-owned foreign exporters are more immune to antidumping measures.

At a time of globalization of business strategies, the solution is not simply to improve antidumping criteria and procedures, but also to develop international cooperative agreements between antitrust authorities, intended to achieve consensus concerning principles and implementation of a world competition policy. Progress is on the way through multilateral discussions (OECD, UNCTC), but also EC bilateral negotiations (with U.S. Federal Trade Commission and Department of Justice; Japanese MITI and Fair Trade Commission).

The main point here is that the distinction between "internal" and "external" competition is more and more blurred given the transcontinental nature of direct investments and the importance of intrafirm trade, the increasing mixing up of the local and international content of final products, the continuous process of delocation of activities all over the world. In such a setting, a strong EC domestic competition policy, coupled with a relatively protective external trade policy, will not only limit the benefits of competition, it will be unable to control effectively the multiplication of restrictive and monopolistic practices in world markets. It is necessary to consider these questions as transnational issues that cannot be solved by unilateral "beggar thy neighbor" initiatives, but will instead require worldwide agreements applicable to "free-rider" countries.

II. Regionalism and/or Multilateralism

Trade economists have long acknowledged that the spatial location of nations plays an important role in shaping trading patterns. (The role of spatial location in

international trade has recently been given a new twist by Paul Krugman, 1990, in the context of increasing returns to scale.) The notion that proximity matters in international trade led European researchers to develop the so-called "gravity model" in the early 1960's. This model postulates that the intensity of bilateral trade flows between two nations is inversely related to the distance between them. Empirical applications of the model have generally defined proximity in a broad economic sense, including geographical, cultural, and institutional dimensions.

Despite their lack of precise theoretical foundation, gravity models have been extremely successful empirically. The natural tendency for countries to trade intensely with their neighbors has long been invoked as a legitimate motive for regional integration. Thus, although the most-favored-nation (MFN) principle was already central, at least as far back as the early nineteenth century, many commercial pacts in Europe allowed departures from MFN obligations on the grounds of either "customs union treaties" or "regional clauses." The latter generally reflected "close ties of sentiment and interest arising out of ethnological, or cultural, or historical political affiliations. *Proximity* was usually a characteristic of the countries so related..." (Jacob Viner, 1950, pp. 18-19, emphasis added).

After World War II, these two exemptions from MFN obligations were enshrined in the Havana Charter for an International Trade Organization (ITO). The Charter recognized "the desirability... of closer integration... [through] the formation of a custom union or a free-trade area" (Article 44). It also authorized the creation of "preferential agreements for economic development and reconstruction" provided certain conditions were fulfilled. First among these conditions was the requirement that "the territories of the parties to the agreement are *contiguous* one with another, or all parties belong to the *same economic region*" (Article 15, emphasis added).

Although the Havana Charter was never implemented, the possibility to establish a customs union or a free-trade area was con-

firmed by the General Agreement on Tariffs and Trade (GATT), provided such arrangement meets a double test: it applies to "substantially all" trade between the partner nations, and it does not raise the level of trade barriers against third nations (Article XXIV). By contrast, GATT did not carry over the provisions of the Charter with respect to preferential agreements among parties that are either "contiguous" or belong to the "same economic region." In the eyes of the founding fathers of GATT, the complete elimination of tariffs among a group of nations, regardless of their geographical location (as in a customs union or a free-trade area) was clearly to be preferred to the partial elimination of tariffs, even among nations belonging to the same region (as in preferential agreements).

This does not mean, however, that the notion of propinquity has had no relevance for GATT-sanctioned customs unions or free-trade areas. On the contrary, the proximity between parties to such arrangements is generally regarded by economists as an important factor in judging their desirability. Thus Paul Wonnacott and Mark Lutz argue that: "Trade creation is likely to be great, and trade diversion small, if the prospective members of an FTA [a free-trade area] are *natural trading partners*." This is more likely to be case if "the prospective members [are] *close geographically*" (1989, p. 69, emphasis added). Thus, a regional integration arrangement that involves the elimination of barriers on "substantially all trade" among nations in close geographic proximity is likely to reinforce natural trading patterns and benefit world trade. As such, it can be referred to as a "natural integration."

The EC fits perfectly well the description of "natural integration," at least as far as manufactured goods are concerned; however, the Common Agricultural Policy (CAP) has modified "natural" trade patterns and resulted in trade diversion. This is confirmed by empirical estimations by Bela Balassa and Luc Bauwens that indicate that the EC has had far less impact on the pattern of international trade than "natural" proximity factors such as geographical dis-

tance and cultural similarity (see their 1989 paper, Table 1). The same should apply to Europe 1992 and the future integration arrangements between the EC and European Free Trade Area countries and between the EC and the countries of Eastern and Central Europe. The key is the external trade policy. These arrangements will be beneficial to world trade provided their external trade policy is liberal.

Until recently, the United States was the champion of GATT and the multilateral system. However, political, economic, and intellectual developments have combined to bring about a new U.S. trade strategy. The "diminished giant syndrome" has brought distrust by the United States in the ability of the multilateral system to serve its interests (see Jagdish Bhagwati, 1990). A strong consensus has emerged in this country in favor of an aggressive, result-oriented trade policy. The new rhetoric did not take long to be implemented. Bilateral actions have multiplied, free-trade arrangements have been signed, and more steps are under way according to a logic of "U.S. trade bloc strategy" (see Rudiger Dornbusch, 1990). Such development, combined with the deepening and widening of integration in Europe and possible regional actions by Japan, has created a sentiment of fragmentation of the trading system into three blocs.

The emergence of a tripolar world puts the future of regionalism at the crossroads. In the years ahead, regionalism can either contribute or be detrimental to the multilateral trading system. The two scenarios are possible, and correspond to a distinction between "natural integration" and "strategic integration." If the three blocs decide to play a noncooperative game, natural integration will be used as a leverage for strategic integration, reflecting the fact that the evolution of integration is not primarily influenced by the *exogenous* trade pattern, but also by *endogenous* trade and industrial policies. (See Jacquemin, 1987, for a similar distinction in industrial organization.) Such a scenario would lead to costly trade wars that may be beneficial to certain nations at the expense of others and/or collectively disadvantageous. This danger is especially

important in activities with large economies of scale and few producers, where strategic policy interventions are already frequent in the EC, the United States, and Japan. On the other hand, a favorable outcome (the compatibility of regionalism and multilateralism) may be possible, provided the three major actors play a cooperative game both among themselves *and* with other nations.

In conclusion, the interconnected internal and external liberalization of the European market, post-1992, can lead to substantial welfare gains. In order to obtain such a global liberalization, credible worldwide agreements about transnational rules of the game are required. Existing GATT rules and disciplines have stood the test of time, but need to be reinforced. It is equally important to recognize that present GATT rules deal only with government interventions. They are silent on everincreasing restrictive business practices. The time has come to enlarge the scope of GATT and consider the establishment of worldwide competition rules.

The Challenges of German Unification for EC Policymaking and Performance

By ROBERT F. OWEN*

Rarely have economists been treated to an economic "experiment" comparable to the one of German reunification. In less than a year, a single political and economic entity is being fused from two economies with fundamentally different underlying principles of economic organization and substantially different levels of economic development. (See Horst Siebert, 1990, and David Begg et al., 1990.) Nonetheless, major regional disparities between western and eastern Germany (what were the Federal Republic of Germany (FRG) and German Democratic Republic (GDR)) will undoubtedly continue for many years. Since the fall of the Berlin Wall on November 9, 1989, both German Monetary Union (GEMU) and political reunification were realized on July 1 and October 3, 1990, respectively. In this process, the advice of economists was often ignored in favor of political imperatives (see Roland Vaubel, 1990).

Concerned with the potential impact of German Economic and Monetary Union (GEMU) on the process of European economic and political integration, many European Community (EC) policymakers have perceived German reunification as adding impetus to the "1992" program. Nonetheless, such initial reactions to GEMU have generally been formulated with only fragmentary information regarding the subsequent economic costs and policy measures, necessitated by the real resource transfer in

order to achieve the German government's stated objective of equalizing living standards between western and eastern Germany. To the extent that GEMU generates positive or negative spillover effects to other EC countries, it presents challenges that can potentially influence the speed and degree of European economic integration.

This paper examines economic implications of GEMU for the European integration process. In so doing, it makes reference to the burgeoning literature on the economic consequences of German reunification. Consideration of statistical information related to the performance of eastern and western Germany since June 1990 permits some evaluation of the validity of certain hypotheses underlying earlier studies of GEMU, as well as an assessment of likely consequences for EC policymaking and performance. Nonetheless, it is contended that the most provocative implications of GEMU result from the specific case it provides for analyzing the costs involved in integrating the fundamentally different centrally planned economies (CPE) of Eastern Europe within a viable European "economic space." In this sense, the German reunification "experiment" offers not only the remarkable opportunity to measure the economic costs associated with the total reorganization and restructuring of a CPE to a free-market economy, but also to assess the contribution of government policy measures in this conversion process. Yet, certain unique characteristics of GEMU limit the validity of lessons from the German experience for understanding the adjustment processes in other Eastern European economies.

I. Conceptual Issues

The macroeconomic consequences of GEMU have been analyzed by Begg et al.

*Associate Professor, European Institute of Public Administration, P.O. Box 1229, 6201 BE Maastricht, The Netherlands; and Researcher, CERCORE, University of Nantes, France. A special thanks is due to Dietrich Hartenstein of the Deutsche Bundesbank for insightful discussions, along with assistance in the identification of German statistical sources. The diligent research assistant of Eugene Canjels, as well as suggestions by Klaus Gretschnann, Jacques Melitz, and Watanabe Shinichi are also gratefully acknowledged.

and by Michael Burda (1990), and their empirical effects simulated in multicountry models by Lewis Alexander and Joseph Gagnon (1990), Paul Masson and Guy Meredith (1990), and Warwick McKibben (1990). A clear consensus, arising from these and other studies, is that GEMU will likely entail some rise in world interest rates and pressures for a real appreciation of the deutsche mark (DM). An associated nominal realignment within the European Monetary System (EMS) has the potential for reducing the credibility of "hard currency" policies that have led in recent years to the convergence of inflation rates in most other EMS countries to those of West Germany, and a narrowing of the range of variations in EMS currencies in relation to the European Currency Unit (ECU). Thus, GEMU has the potential for affecting the prospects for European Monetary Union (EMU)—the final stage of which is targeted for January 1, 1997.

One rationale for a real DM appreciation focuses on the inflationary impact of the additional export demand from East Germany—particularly for investment goods. Given the near-capacity level of many firms in the FRG, real exchange rate appreciation is a mechanism by which German industry would become increasingly specialized in capital goods production, while imports of consumption goods from other countries would increase, but perhaps temporarily. Capital inflows to Germany, induced by favorable investment opportunities and higher real interest rates, could compound this tendency for a DM appreciation, which Begg et al. have characterized as "overwhelming" (p. 65). While such pressures on the DM will depend on the specific fiscal and monetary policies adopted in Germany, a probable scenario is for only limited, additional tax financing and continued restrictive monetary policies by the Bundesbank. Hence, the real resource transfer to eastern Germany, will likely generate a substantial government budget deficit.

A consequent dilemma appears to confront adherents of a fast move toward EMU. Rather than permitting an EMS realignment that could be perceived as weakening

the prospects for attaining the third stage of the Delors plan, other EMS currencies may be allowed to appreciate with the DM. Such a prospect, along with higher real interest rates, suggests a scenario where GEMU entails a slowdown of economic activity elsewhere in the EC. However, in the longer term, other factors, such as a deteriorating trade balance and a lower per capita GNP for an unified Germany (relative to the FRG), could entail a DM depreciation. Thus, the size of the real resource transfer to eastern Germany appears critically related to the potential for short-term, exchange rate overshooting.

The foregoing analysis suggests that the implications of GEMU will be influenced by changes in the external position and commodity composition of Germany's trade, as well as by a likely Germany fiscal deficit. As noted by Daniel Gros and Alfred Steinherr (1990), a high, East German propensity to purchase consumer goods produced by other EC countries dampens pressures for an initial appreciation. A related issue concerns the degree to which increased demand for capital goods and related intermediate components will be skewed towards German producers. Although Begg et al. highlight the dominant positions of West Germany and Japan as net exporters of machine tools and other engineering goods, other European producers, such as Switzerland and Italy, may also be beneficiaries. Excessively high, resource transfer costs due to GEMU could jeopardize German commitment to the additional distributive support for "Southern Europe," provided by the so-called "flanking policies" of the Delors plan for EMU. As analyzed by Paul De Grauwe (1990), the precipitous supply-side shock to the GDR's economy might lead to a "Mezzogiorno syndrome," whereby a permanently disadvantaged region is created in eastern Germany, requiring massive resource transfers for many years. Giorgio Basevi (1990) suggests that such potentially large regional disparities could revitalize the "two speeds approach" to European integration. According to this argument, a divergence could arise in the pace that certain countries would be willing to undertake in-

stitutional changes towards European integration.

In view of severe economic difficulties and uncertainties facing the fledgling democracies in Eastern Europe, GEMU provides a remarkable "experiment" that can offer insights regarding the role and costs of government policies in the transformation process from centrally planned to free markets economies. Major issues concern the viability of producers in eastern Germany, costs of resource transfers, immigration pressures, optimal privatization policies, the responsiveness of private-sector capital flows to investment opportunities, and the efficacy of alternative public investment initiatives. The "shock therapy" of GEMU, wherein eastern German firms must rapidly face national and international competition, may result in a speedy transformation process or generate a Mezzogiorno-type economy. Nonetheless, certain unique aspects of German reunification limit the validity of inferences for other Eastern European countries. The automaticity with which West German legal institutions have been adopted eschews highly conflictual issues related to the assignment of property rights, creating a more favorable investment environment. Other differences include the overriding commitment of the German government to equalize living standards (as represented by the German solidarity fund), the substantial transfer of purchasing power to East German consumers resulting from GMU, along with the monetary discipline of the Bundesbank. Finally, the higher standard of living, stronger productive sector, and lower international indebtedness of the GDR also warrant consideration.

II. Macroeconomic Simulation Results

Econometric simulations of GEMU, including those previously cited, indicate a dependency of estimated results on alternative German policy responses and an hypothetical EMS realignment. Yet, perhaps the most pervasive characteristic of these studies is the relatively small magnitude of the estimated effects. For example, based on simulations of the IMF's global model,

Masson and Meredith found an upward pressure on long-run real interest rates in the FRG of $\frac{3}{4}$ of a percentage point, a modest, $3\frac{1}{2}$ percent real appreciation of the DM relative to the dollar, and a reduction in West Germany's current account surplus equaling 2 percent of GNP. Other effects on the rest of the world were generally small.

Similarly, McKibbin's simulations based on the McKibbin-Sachs dynamic multicountry model, show that if the GDR is initially taken as a "separate economic entity outside the model" (p. 8), an anticipated fiscal expansion leads to an increased German fiscal deficit by 3.3 percent of GDP as of 1991, a 1 percent rise in world interest rates, and a 7.7 percent appreciation of the DM in relation to the dollar. Under the alternative scenario of a unified Germany, McKibbin found a net 8 percent increase to total unemployment after the first year. Nonetheless, such econometric results are based on preunification models that do not explicitly incorporate estimates of either the microeconomic costs associated with restructuring East German industry, or the associated pressures for real resource transfers.

III. Recent Empirical Evidence on the Performance of the GDR¹

Two particularly striking features of GEMU since June 1990 are the surge in exports from western to eastern Germany and the virtual collapse of eastern German industrial output. Specifically, inventory accumulation in anticipation of GMU generated exports from the FRG to the GDR for June equal to 312 percent of the May value. Similarly, overall purchases from West Germany by the GDR, during the 5-month period beginning in June, were 3.57 times those of the corresponding months in 1989. This precipitous jump dwarfs the comparable

¹Unless otherwise indicated, the statistical information cited here is based on published series from Deutsche Bundesbank and the Federal Office of Statistics.

multiple of 1.23 for imports from the GDR, leading over this period to an overall, 8.2 billion DM trade imbalance. Furthermore, accumulated FRG sales of investment goods to the GDR, from June through October 1990, have risen dramatically to a level 3.29 greater than the corresponding 5-month period a year earlier. These constituted 36.3 percent of total exports from the FRG to the GDR over the more recent period. Nonetheless, the increases for food products, raw materials, and other consumption goods exports are also substantial (in corresponding order, 11.50, 1.49, and 35.5 times greater), while their respective shares of the 5-month total are 27.5, 17.2, and 9.3 percent.

The prospect of positive spillover effects for a number of EC countries is also suggested by their improved trade balances with Germany, reducing immediate pressures for a DM appreciation. Specifically, over the 5 months since June, the value of West Germany's imports from the EC rose by a monthly average of 9.5 percent (relative to the same months in 1989), whereas imports of the EC decreased by 3.9 percent. Yet, the substantial variance across EC countries in the average monthly changes in their exports to Germany, as well as differences in the levels and propensities of exports to the German market, suggest that the country-specific effects of trade generation resulting from GEMU need to be examined in more detail. (During the 5 months, the largest monthly increases of exports, again, relative to 1989, were from Denmark, Belgium plus Luxembourg, and Italy, that equaled 16.5, 12.2, and 11.2 percent, respectively. In comparison, the value of exports from Japan rose by 3.1 percent, while those from the United States fell by 8.6 percent.) In fact, there is a quite low correlation coefficient of .17 between the shares that exports to West Germany represent in each EC country's global exports, on the one hand, and the total imports of the FRG, on the other (based on OECD COMTAP trade data for 1987). Hence, it is apparent that any simulated net contribution of GEMU to Germany's aggregate macroeconomic performance can be associated with quite dif-

ferent trade multiplier effects across the different EC economies.

East Germany's industrial output had fallen by September 1990 to a level 51.1 percent below its level in the same month of the previous year. Associated with this dramatic production loss is the more gradual, but steady increase in unemployment. The 589,200 unemployed in November constituted 6.7 percent of the work force in eastern Germany. While the threshold of what will be the lowest level of eastern German production remains to be observed, unemployment in eastern Germany appears to be lagging the more precipitous production downturn. This portends an ominous omen for any realistic assessment of the resource transfers that will be necessary to provide unemployment compensation and subsidies to mitigate continued migration pressures. Indeed, in light of such rapidly rising government expenditures, recent estimates of the German budget deficit for 1991 (cited in the German press) have been as high as 150 billion DM, or between 5 and 6 percent of forecast GNP. This suggests the necessity of reassessing simulations of the global impact of GEMU.

IV. Conclusions

In the course of examining the implications of GEMU for the European integration process, an initial focus on the macroeconomic performance of a united Germany highlighted the potential pressures for a short-term real appreciation of the DM, an increase in real interest rates, a German fiscal deficit, and a foreign capital inflow into Germany. Depending on the commodity composition of the trade generated by GEMU, and the dominant position of West German producers in the capital goods industry, there will also be associated effects on trade flows between Germany and the rest of the world. However, the magnitude of estimated results obtained in recent econometric simulations of GEMU suggest relatively small spillover effects for other countries' performance.

A contention of this paper has been that perhaps the most intriguing aspect of

GEMU is the "experiment" it provides for assessing the adjustment costs involved in converting a centrally planned economy to a market economy. This, in turn, suggests that the validity of using existing models to simulate GEMU ultimately depends on a series of empirical issues related to the postunification performance of East Germany. In this latter regard, initial empirical evidence reveals an unidirectional surge of exports from West to East Germany, the collapse of the supply side of the GDR's economy, an associated build up in the German fiscal deficit, as well as dampened German exports, but substantially higher imports to Germany. The latter appear to be rather unevenly spread across countries, and by no means confined to capital goods. Certain of these effects appear to have been insufficiently characterized by existing empirical work, suggesting the methodological inadequacy of relying on simulation approaches that do not explicitly model the GEMU process. Clearly, the GEMU phenomenon will not only generate intra-German and international trade, but also a substantial research agenda. In this latter regard, one intriguing issue concerns the interrelation between internal and international investment flows for Germany, and the trade patterns identified here.

Integration of Eastern Europe into the World Trading System

By HELEN B. JUNZ*

One year after the historic decisions of almost all Eastern European countries¹ to change their economic orientation toward guidance through market signals, the stark realities of that decision have become clear. They are the more apparent as the efforts at economic reform break decisively with the past. Previous such attempts generally sought to find ways of cohabitation for what remained essentially different economic systems, including a way to operate within a multilateral trading framework. Today, these countries no longer seek a way to live in a world with a different economic orientation, but rather to adapt themselves to be part of that world and to regenerate linkages that have been stunted during decades of politically determined, inward-looking economic development. In short, they look to political and economic transformation. Thus, the fundamental question no longer is "why cannot they be more like us?" but, now that they have decided to be like us, "what is the most efficient, therefore least painful, way of doing so?" This leads to the basic question: how deeply rooted are their present regional links, as manifested in the CMEA,² not only in terms of trading relations, but also in terms of employment and production structures, and what rigidities do they bespeak?

This question is virtually impossible to answer with any degree of precision as, in an environment that put a high premium on administrative success, so-called factual information does not necessarily reveal hard facts. Data, thus, are a mixture of fact and fiction. But it is a fact that the CMEA group has traded on the basis of raw material inputs, particularly energy, at below world market prices. This has led to capital stocks and production structures that, in market terms, are wasteful; as capital structures have been maintained well into technological senility, it will not be easy to shift resources from supplying command-economy markets to satisfying market-based demands. Although the breadth of this problem cannot be gauged, indicative numbers show that, for example, Hungary's and the CSFR's output of machinery and engineering products are deeply regionally intertwined, with about 30 percent for use in other CMEA countries. Such numbers show that integrating these economies into the high-tech, highly competitive markets of the West will prove a daunting task.

Why is this so? First, there is the sheer size of intra-CMEA trade (between 40 to 80 percent of members' overall trade). This trade moved largely under long-term contracts and provided a certainty of production runs and, therefore, also of employment. This in turn produced managerial attitudes not well adapted to facing the uncertainties inherent in a competitive situation. Second, production based on these arrangements was not able to earn its way: the trading unit of account, the transferable ruble, was considered by most participants to be highly overvalued against other CMEA currencies; this meant, in many cases, that fulfilling CMEA contracts required varying levels of subsidization from national budgets. Moreover, even though in most countries the price structure floated on low-priced raw material inputs, a large part of

*Special Trade Representative and Director, International Monetary Fund, 58, rue de Moillebeau, 1209 Geneva. The views expressed are those of the author and not necessarily those of the Fund.

¹Bulgaria, the Czech and Slovak Federal Republic (CSFR), Hungary, Poland, Romania and, until mid-1990, the German Democratic Republic.

²Council for Mutual Economic Assistance, the regional economic organization charged with monitoring trade and payments and promoting specialization of production. Its members are: Eastern Europe listed in fn. 1, the USSR, Cuba, Mongolia, Vietnam, and Albania (inactive); Yugoslavia is an associate member; Afghanistan, Angola, Ethiopia, Finland, Iraq, Mexico, Mozambique, Nicaragua, and Yemen have cooperative links; in addition there are numerous observers.

output, because of design and quality problems, could not have obtained even the CMEA price in Western markets.

Integration of these economies into the world trading structure involves the whole complex of structural adjustment policies, including the need to surface, and then to eliminate, the subterranean inflation and unemployment that have cumulated during more than a generation of command-economy management. Thus, the problem is how to do away with multiple pricing, direct and cross subsidization, absorption of resources by noneconomic activity, suppression of inflation and unemployment; in short, stripping away the administrative economic cocoon to reveal the butterfly of comparative advantage. All this, obviously, cannot be achieved overnight, but the risk that opportunity might flutter by is high.

In these circumstances, the main questions are: 1) What is the best institutional environment in which comparative advantage can be revealed, uneconomic activities weeded out, and policy credibility and public support (the two being essentially mirror images of each other) maintained? 2) At what speed should adjustment take place?

In considering these questions, the centrally planned economies in process of transformation often have been viewed as a cohesive group (i.e., a bloc), susceptible to a generalized policy prescription. Clearly, this "bloc mentality" belongs to the past. Each of these countries has different characteristics, for example, with respect to resource endowment and to the institutional and political capacity to support and sustain change; these differences impact the structure and possible speed of economic transformation. Even so, some general points apply.

First, any policy reform package must be comprehensive. This is so because the main elements of a market economy are interrelated; for example, successful price reform is not possible if channels for transmittal of price signals do not exist or are clogged. This means that wage reform, acceptance of financial responsibility by enterprises, and reform of the financial sector must go hand in hand with the move to market prices.

Experience shows that piecemeal reform, such as tried by Hungary and Poland prior to 1989, does not succeed. In fact, a piecemeal approach carries the seeds of policy reversal within itself; such reversal, in turn, progressively undermines effective policy implementation because each such episode erodes policy credibility and, thereby, increases reaction lags by reform-minded entities, while shortening those of vested interests. Thus, clarity of purpose and predictability of policy action are a *sine qua non* for the success of reform strategies.

Second, it is obvious that comprehensive reforms, particularly when distortions are deeply rooted, cannot be implemented overnight. In fact, Adam Smith already saw this:

The case in which it may sometimes be a matter of deliberation, how far, or in what manner, it is proper to restore the free importation of foreign goods, after it has been for some time interrupted, is, when particular manufactures, by means of high duties or prohibitions upon all foreign goods which can come into competition with them, have been so far extended as to employ a great multitude of hands. Humanity may in this case require that the freedom of trade should be restored only by slow gradations, and with a good deal of reserve and circumspection. [1937, p. 435]

While one must agree with Smith that too fast a speed could undermine support for the right policies, it also is true that too slow a driver may cause as many accidents as a speedster. The need to find the realistically safe and sustainable speed for implementation of reforms, however, must not be confused with the tendency to delay politically and socially difficult actions under the name of "gradualism." Thus, the natural uncertainties of the market must not be compounded by uncertainties about policy action; and the pace of implementation must be sufficiently fast to allow an early harvest, but not so fast as to outpace the institutional change without which operational measures cannot have their intended effect.

The need for the reform effort to move forward on a broad front is rooted in the need to generate an investment structure adapted to today's and to future economic facts. But some imperatives of reform are more equal than others. First, if the reform effort is to succeed, economic accountability at all levels, enterprise management, government and individual, is a must, particularly as sanctity of contracts generally has not been a feature of the command economy. De facto accountability has to be accompanied by the development of a judicial system that governs private sector transactions and provides predictability. These are the preconditions for sound longer-term investment and the generation of investable savings. They are the more urgent as the scarcity of available resources, financial, budgetary and real, leaves virtually no room for mistakes.

Third, reform must be accompanied by trade liberalization to help break down domestic monopolies and to gain the efficiencies from the division of labor across borders. In increasing links to the rest of the world, Eastern Europe has looked to close involvement with the three international economic organizations—the IMF, World Bank, and GATT. Most Eastern European countries are GATT members of long standing.³ But their economic systems did not allow them fully to meet the GATT requirements on reciprocity, nondiscrimination, and transparency, and, in the absence of market pricing, caused adoption of special safeguards by other members to guard against possible dumping by state-trading organizations. With adoption of price guidance, these countries should become fully functioning members.

This raises a set of problems, but also opportunities, some of which are closely intertwined with the reform process: how fast can subsidies be dismantled, and what are the consequences of shifting from essen-

tially barter to trade in convertible currencies? In this respect, a central question is whether halfway houses provide positive help toward making these economies internally and externally competitive. As long as a significant part of the existing capital stock remains in use, some sizeable intra-CMEA trade, if only in spare parts, will continue to exist. In addition, the existing infrastructure (transport links, ability to off-load and process raw materials, especially oil) also mandates continuation of CMEA trade. Finally, the shift to market pricing will improve the USSR's terms of trade and associated potential financial strains could impact the intended move away from countertrade. This potential has given rise to proposals for a Central European Payments Union (CEPU) among a varying number of CMEA countries (excluding the USSR). This is seen as easing the road to external convertibility and maintaining what are thought to be natural economic links among neighboring countries. However, as the main regional payments problems would arise vis-à-vis the USSR and the need is to build channels to markets and suppliers outside rather than within a truncated CMEA, the rationale for a CEPU seems not soundly based; in effect, it might lead to permanent occupation of the halfway house. This in no way means to minimize the financing problems that are likely to arise once normal production levels are reestablished and import demand recovers from its currently depressed levels. However, more direct avenues would seem to provide better solutions.

Developments in 1990 bear this out. The fast integration of East Germany into a unified Federal German Republic, which has cut deeply into CMEA flows, efforts by reforming countries to reorient their trade toward Western markets and the sharp falls in domestic output and demand, all have caused intra-CMEA trade to contract. Consequently, it is estimated to have fallen by some 20 percent in volume in 1990. This trend could accelerate with the dissolution of the traditional CMEA and the move, in principle, to trading at world market prices and in convertible currencies as of January

³Bulgaria is in process of accession and the USSR became an observer in early 1990.

1991. In anticipation, a large number of bilateral barter deals are being concluded, both government to government and enterprise to enterprise. However, future trends in intra-CMEA trade are likely to bear little relation to current deals as input needs over the medium term, and legal and managerial decision-making ability of enterprises, are uncertain. Another factor is the past history of elastic interpretation of contracts.

On the whole, anticipation of changes in the regional trade and payments system has aimed to reduce bilateral imbalances, particularly, but not exclusively, vis-à-vis the USSR. This included both exchange rate and administrative measures. The basis for new contracts largely involves cash settlements and supplier credit arrangements, rather than, as earlier anticipated, special clearing arrangements that emphasize regional ties. But, with inter-enterprise relations still embryonic, barter deals may continue to dominate for some time. Even so, the effects of changes in the relative prices of intraregional trade will put further pressure on the pace of adjustment: obsolescence of whole branches of production will surface more clearly and, consequently, also the need to restructure capital stocks; but this, in turn, will complicate the digestibility of adjustment efforts as social pressures, particularly those associated with rising unemployment and inflation, will be exacerbated.

At the same time that old trading relationships disintegrate faster than anticipated, integration into the world trading system remains time consuming. The "early harvest" that followed removal of disincentives to market-oriented trade (particularly in agriculture and consumer goods) probably is beginning to run its course; further export growth, consequently, must rely on restructuring of production, including the ability to respond flexibly to emerging and changing demand stimuli. This is more urgent as the events in the Persian Gulf have shrunk traditional markets and increased world energy prices. Although the latter should help rationalize energy use, it may overload the adjustment circuits.

As recent developments show, the region cannot really look to intraregional trade to cushion the process of integration of its production structures into the world economy. This makes a durable acceleration of expansion of trade relations with the rest of the world yet more pressing. Therefore, it is not surprising that these countries, with Poland, Hungary, and the CSFR in the vanguard, are seeking special access to the markets closest to them. Thus, they are in the process of negotiating association agreements with the EC and look to free-trade negotiations with European Free Trade Area. More broadly, adoption of market pricing and abrogation of state trading, as noted above, provides the basis for full integration into GATT. This involves introduction of nondiscriminatory and largely bound tariffs at economically justifiable levels and, for other GATT members, abolition of their special safeguard clauses. A national tariff structure for Eastern Europe obviously requires that relative prices reflect comparative advantage domestically and externally. This goal is undercut by the external trade restraints that exist in many markets, as these are an impediment to rational resource allocation, especially important during the transition period.

Equally important, the ability to increase exports in the face of large import-intensive investment requirements is crucial if external viability is not to be compromised by excessive levels of external debt. Eastern Europe has a known comparative advantage in agriculture and in certain soft goods and, once technological bars are lowered, will compete in high-tech areas on the basis of a highly educated labor force. These are exactly the trading areas that are rife with structural barriers in the most promising markets in Europe and elsewhere, and where head-on competition is likely to engage producers in both developing and industrial countries. This is an additional element in the effort of Eastern European countries to negotiate special agreements with the EC, which in turn has raised fears on the part of current suppliers both EC-associated (such as Maghreb) and nonasso-

Industry Restructuring in East-Central Europe: The Challenge and the Role for Foreign Investment

By CATHERINE L. MANN*

Two key reforms underpin the moves toward more market-oriented economies in East-Central Europe (ECE): price reforms that allow a freer alignment of relative prices toward international norms; and industry reforms that increase competition, flexibility, and efficiency. These reforms are linked; only competitive firms responding to rational price signals can create an industrial structure able to withstand the rigors of international competition.

I. The Challenge of Changing Industrial Structure

Privatization is the transfer of ownership from the state to the private sector and is the hallmark of the market-oriented reform programs. But a market economy cannot be built from privatized enterprises alone, because the existing industrial structure of the East-Central economies lacks robust midsize enterprises. Midsize firms in industrial market economies transmit price signals and absorb shocks to employment and output. Thus, industry restructuring in ECE requires both privatization and new enterprise creation, particularly of midsize enterprises.

The concentration of ownership in state hands is clear.¹ In the Czech and Slovak Federal Republic (CSFR) as of 1989, 90 percent of industry was state owned and was so monopolized that 60 percent of the inputs to final production were sourced from

single plants. In Hungary, state-owned industrial enterprises accounted for 80 percent of the value of output in 1987, private enterprise less than 2 percent.

A second legacy of the command system is a dearth of midsize enterprises. Although hard to define precisely, the midsize enterprise is between the "atomistic" entrepreneur and the large corporation in terms of production complexity, employee size, and economic power. The midsize enterprise has greater fixed and working capital investment, greater demands for organized labor input (as in a team or on a production line), and requires more management than a small enterprise, but it is too small to wield any power over input or output markets. Such an enterprise could be a subsidiary of a large corporation so long as it remains a separate decision-making unit operating at arm's length.

The midsize enterprise plays several important roles in the market economy. As producers of intermediate inputs and niche-market products, midsize enterprises increase diversity of output and flexibility and efficiency of production. As distributors and wholesalers in internal and external trade, midsize enterprises link the larger firms to each other and to the final consumer. As the competitive core of the economy, they channel and refine the price signals between producers and consumers.

Judging what is an appropriate mix of enterprise sizes for an economy requires knowledge of output markets and production technology of leading industries, and an understanding of the lines of corporate financial and managerial control. Nevertheless, data suggest that East-Central economies lack independent midsize decision-making units in both manufacturing and trade.

In industrial market economies, small and midsize firms are the core of the economy.

*Staff economist, Division of International Finance, Federal Reserve Board of Governors, Washington, D.C. 20551. This paper represents my views solely and should not be interpreted as reflecting those of the Board of Governors of the Federal Reserve System or of other members of the staff.

¹Data are from national statistical yearbooks, interviews with government officials, and translations of newspaper articles and publications of economic institutes.

Considering manufacturing alone, the vast majority of firms (more than 85 percent) employ fewer than 100 people but account for about a third of manufacturing employment and about a quarter of the value of manufacturing output. Midsize firms (between 100 and 500 employees) account for about 10 percent of firms, and a third of both employment and output. Data for the Netherlands (which is similar in population to Hungary and the CSFR) indicate that midsize establishments also account for about a quarter of export sales.

The legacy of the command system makes the enterprise the relevant decision-making unit in ECE. The CSFR has the most centralized manufacturing structure. In 1987, 66 percent of employment was in large enterprises (1000 to 5000 workers). Small enterprises (less than 500 people) accounted for less than 2 percent of employment; data for smaller enterprises are not available.

Hungary has a more diversified industrial structure in large part because industrial cooperatives have been allowed to develop along side the state enterprises. The state industrial enterprise remains the dominant economic unit in manufacturing, employing 85 percent of the work force and accounting for 92 percent of total industrial output in 1988, although there are about equal numbers of industrial state enterprises and industrial cooperatives in manufacturing (somewhat more than a thousand each). Midsize state enterprises (100–500 employees) accounted for 12 percent of all state firms, and only 9 percent of total employment and output. Large state enterprises (greater than 500 employees) accounted for 18 percent of firms, 83 percent of employment, and 40 percent of output. Most industrial cooperatives were midsize; even though their impact on the economy is small, Hungary would have no midsize firms at all without the cooperatives.

Midsize enterprises increase the complexity of linkages throughout an economy, which is why their existence was incompatible with the command system. However, robust growth of midsize enterprises would ameliorate the strains associated with ratio-

nalizing the state-owned sector and would speed price reform.

II. Privatization and Midsize Enterprise Creation

Privatizing the state-owned sector will not create the web-like industrial structure characteristic of market economies, but it is a necessary adjunct. Likewise, legislation supporting privatization does not equate to encouraging new private-sector development. Accordingly, two additional facets of industrial restructuring are the degree to which private investors can restructure existing firms that are inefficiently organized, and the extent to which bona fide new enterprises have equal access to credit, labor, and other inputs, as well as product markets. In a sense, this second facet represents the outcome of the whole reform process.

Foreign investment can play an important role in industry restructuring, particularly through midsize joint ventures. The joint venture may be particularly promising both for foreign investors and for the countries. The foreign investor may prefer the joint venture because he gains immediate access to the target sector without waiting for an existing enterprise to come up for privatization. Moreover, he can bargain for a majority share from the start (less likely in the large privatizations) and avoid many of the nationalism and employment issues associated with large privatizations. Finally, capital required to engage a foothold in a risky foreign market is generally lower with the joint venture.

For the countries, as well, foreign investment in joint ventures may be the best way to obtain the technology, management expertise, and Western contacts they desire. Joint venture activity may point to the most promising external markets. Because of their size, joint ventures create the base for a dynamic midsize sector. Finally, because some of the credit, talent, and inputs are foreign sourced, a joint venture can create a more level playing field for itself, thereby aiding the overall reform process.

Legislation legalizing or broadening forms of new private enterprise and removing lim-

itations on sales, number of employees, and foreign participation was passed in the last 2 years in Poland, Hungary, and the CSFR. All three countries also are privatizing small state-owned establishments and have moved forward on large privatizations.

Structural change is evident in all three countries. In Hungary, between 1987 and mid-1990, the private sector's contribution to overall economic activity increased from 2 to nearly 20 percent. Two thousand new firms with less than 50 employees opened in 1990, more than doubling the number from 1989. In the first 8 months of 1990, economic activity at midsize enterprises greatly outstripped that at small and large enterprises; aggregate industrial production fell 10 percent, but firms employing between 50 and 300 people increased output by 21 percent.

In the CSFR, the number of private enterprises rose 50 percent between June and September 1990 to 340,000. The main areas of growth were in repair, custom work, building, trade, and personal services. Moreover, in advance of the start of large privatizations, some Ministries broke up their enterprises, doubling the number in the industrial branch to 225 and increasing by fourfold the number in the engineering branch to 366.

In Poland, private enterprise has increased even though the macroeconomic downturn has taken its toll. In the first 5 months of 1990 (the worst part of the recession), 10,000 new private enterprises per month were registered. The most successful appear to be in trade. The registered private sector accounted for 8.8 percent of industrial production, but some estimates put its importance at above 20 percent.

One difficulty in tracking the impact of the burgeoning private sector is lack of information. Some private entrepreneurs have reinterpreted the democratic political reforms in the economic realm—they neither register with the taxing authority or submit economic data to the statistical offices.

The difficulty of establishing clear ownership, tensions between equity and efficiency in privatization schemes, the nexus of ownership vs. control issues, and nationalism

have made large privatizations rather contentious. In all three countries, large privatizations are moving forward slowly, but foreign investment appears to have a minority role.

In Poland's large privatization program, shares of the firms are allocated to different uses, including recapitalization of the banks, funding social security, and so on. Foreign investors desiring a large stake may negotiate with the state and workers, but a 40 percent share would appear to be the upper limit. Of the five enterprises offered for sale in December, none allowed majority foreign ownership.

Legislation governing large privatization is still being discussed in the CSFR, but outlines of the program are clear. Although majority foreign ownership is possible, in that between 40 and 80 percent of a firm will be sold to domestic or foreign investors (with the remaining portion distributed to the population via a voucher system), majority foreign ownership is unlikely to be observed in fact.

In an effort to move more quickly and to depoliticize the process, Hungary's State Property Agency solicits bids from private investment banks for the right to privatize a state enterprise. Even so, most of the tenders have had restrictions on the share of foreign ownership. However, Hungary has a midsize enterprise privatization program that allows greater foreign participation.

In addition to transferring ownership from the state, another objective of the large privatization programs is to restructure firms. In the Hungarian and the CSFR large privatization programs, the investor can break up the enterprise before buying it, handing back to the state functions that do not make sense in the context of a restructured firm. Foreign investors are seen as important guides in this restructuring process. But limiting foreign ownership to a minority position may reduce the interest and ability of foreign investors to play this role.

The joint venture, whereby the state and a foreign investor create a new enterprise in an industry sector, is a parallel track for industry restructuring. The foreign firm

leads, usually with majority ownership, while the state facilitates by leveling the playing field, often through tax holidays. Joint ventures are still relatively small in the marketplace, accounting for only a few percent of economic activity, but they have been growing quickly in all three countries. Many are midsize firms in the most profitable sectors.

In Hungary, about 4500 joint ventures were registered as of August 1990, up from only a 100 or so in 1988. Data for 1989 suggest that the joint ventures were more profitable than the state-owned firms in similar industry branches and accounted for just less than 10 percent of total industry profits earned in the economy. By industry branch, 45 percent were in engineering and these were the most profitable. Light industry and chemicals also received foreign capital infusions. Sectors of emerging interest are tourism, software, and financial, consulting, and accounting services. In contrast to the large privatizations, about a third are majority foreign owned, with somewhat less than a quarter fully foreign owned. Early statistics for 1990 are similar although it appears that the average capitalization dropped between 1989 and 1990 from about \$400,000 per firm to about \$225,000 (some of this may represent exchange rate changes). This represents a smaller foreign infusion than the price of a lower share in a large privatization.

In Poland, about 1500 joint ventures have been registered. Of the 30 largest, 4 each are in the food and hotel industries, with other ventures in furniture, agricultural machinery, and environmental engineering. Forty percent have a majority foreign stake, with 25 percent having a 90 to 100 percent foreign ownership share. Compared to Hun-

gary, the asset value is somewhat smaller, with 18 percent having a value of \$60,000 to \$100,000 and 33 percent less than \$50,000.

In the CSFR, the joint venture is the only way to enter the market, since the privatization program has not yet begun. Nine hundred joint ventures were established as of November 1990, with the number doubling in November. Foreign investment appears to be concentrated in expanding sectors: 25 percent of joint ventures were in engineering and 20 percent in ceramics and glass. As of the third quarter, industrial production overall was down by 3.7 percent over the same period in 1989, but the glass, ceramics, and china sector increased production. Twenty percent of all joint ventures are 100 percent foreign owned. On average, the foreign ownership share is 77 percent.

III. Conclusion

Being incompatible with the former system, East-Central Europe has a few midsize enterprises. A robust midsize sector could aid price reforms, absorb some of the output and employment losses associated with rationalization of the large state enterprises, and provide a wider range of consumer goods.

Foreign investment through joint ventures may be the best way to underpin the reform movement. Joint ventures benefit the investor by giving majority control with a smaller investment, and by allowing entry into a market without the burdens of large privatizations. The joint venture benefits the country by developing a midsize sector to channel Western technology, expertise, contracts, and credit to the most dynamic parts of the economy.

ECONOMIC DEVELOPMENTS AND PROSPECTS IN CZECHOSLOVAKIA, YUGOSLAVIA, AND GERMANY

Czechoslovakia: Recent Economic Developments and Prospects

By KAREL DYBA AND JAN SVEJNAR*

Czechoslovakia provides a unique example of a country that became underdeveloped as a result of an externally imposed system. Before World War II, Czechoslovakia was a democracy, with GNP per capita similar to that of Belgium and Austria. Its industries were on the technological edge and its products were known worldwide for their superb workmanship. By 1990, Czechoslovak GNP per capita is estimated by the World Bank at \$3,300, thus being comparable to that of Venezuela, Gabon, and Yugoslavia, but only slightly above one-fifth of that of Austria and Belgium.¹ Most Czechoslovak products are now of mediocre quality and selling at a discount, if at all, in the West.

This remarkable transition occurred over approximately 40 years. During the post-World War II reconstruction, the country was still run as a market economy, although major parts of industry, banking, and insurance were already nationalized. After the 1948 Communist takeover, Soviet-type economic planning was imposed, the remaining private enterprises were nationalized,² and priority was given to heavy industry. Czechoslovak foreign trade was reoriented from world markets toward Soviet bloc countries.

*Czech Minister for Economic Policy and Development, Trida SNB, Praha-Vrsovice, Czechoslovakia, and Professor of Economics, University of Pittsburgh, 4M30 Forbes Quad., Pittsburgh, PA 15260, respectively. The views expressed in this paper are our own and do not reflect the official positions of the Czech government. We thank Vladimir Dlouhy for useful comments.

¹The estimated GNP of Czechoslovakia naturally depends on the methodology used. Some other studies generate higher estimates.

²Private agriculture was collectivized or converted into state farms.

The Czechoslovak government adhered to the Soviet-type planning system faithfully throughout the 1950's. The economic slowdown in the early 1960's led to a series of reform attempts, that culminated during the Prague Spring of 1968 with a short-lived and partial program of price liberalization, separation of economic policy from political decision making, enterprise autonomy, and workers' participation in enterprise management. However, central planning was reimposed after the 1968 invasion and remained virtually intact until the late 1980's.

I. An Historical Overview of Economic Performance

Even if one were to treat the current estimates of Czechoslovak GNP per capita as downward biased, the profound decline of Czechoslovakia's standing relative to advanced market economies is undisputable. As a result, one has to accept the official as well as Western data on Czechoslovak economic growth with caution. The data indicate that the most impressive rate of growth occurred during the First Five-Year Plan (1949-53), when the officially measured net material product (NMP) increased at nearly 10 percent a year. However, this pace proved unsustainable and in the second half of the 1950's, NMP grew at 7 percent annually. The 1961-65 period witnessed virtual stagnation and led to the subsequent reform. Growth resumed at about 7 percent during the 1965-70 reform period and the economy still registered almost 6 percent annual growth during the following 5 years. A major slowdown to 3.6 percent set in between 1975 and 1980 as the first oil shock turned the terms of trade against Czechoslovakia

within the Council for Mutual Economic Assistance (CMEA) and agriculture recorded poor performance.

As can be seen from Table 1, the 1980's witnessed a further slowdown in economic growth. The 1.8 percent growth in the first half of the 1980's reflected the impact of the world recession, rising input prices, and restrictive government policies. However, even in the 1985-89 period, the growth rate was only 2.2 percent a year. With many observers noting that inflation was being increasingly underestimated, the 1980's can arguably be seen as a decade of economic stagnation (see Dyba, 1989).

Other indicators also signaled deterioration in economic performance. The share of net fixed investment in NMP fell from 20 percent in 1975 to a mere 13 percent in the late 1980's, and the share of consumption rose. Export growth slowed down in the 1980's and exports to economically troubled developing countries were increasingly accompanied by trade credits. Within CMEA, Czechoslovakia became a net creditor, especially vis-à-vis the USSR and Poland.

The secular deterioration of economic performance was brought about by a number of factors. The centralization of all economic activity after 1948 initially created phenomenal growth as the command system could rapidly mobilize existing resources. The other engine of growth was the rapid increase in inputs that temporarily sustained respectable growth rate. The shortcomings of the centralized system that gradually became overwhelming were the perverse incentives, limited innovation, inefficient allocation of resources, and rigidities. These latter factors became especially important as input growth could no longer be sustained at high rates, and the quality of marginal inputs declined. The situation was further aggravated by the isolation of Czechoslovakia from world markets and its extreme reorientation on trade within the CMEA. This reorientation contributed to the increasing technological backwardness of Czechoslovak industry and vulnerability to disruptions in the protected CMEA markets.

II. The Start of Economic Transformation, 1988-90

A number of initial reform steps, undertaken in 1988-90, pave the way toward more substantial changes that are to take place in 1991 and thereafter. Even before the November 1989 "Velvet Revolution," the Communist government had reduced the role of central planning somewhat. The November 1989 revolution ushered in a liberally oriented transitional government, and created strong expectations of a radical economic transformation from a centrally planned to a market economy. A number of domestic as well as some external proposals (see Svejnar, 1989) for the strategy of economic transformation appeared, but disagreement also emerged within the government about both the overall direction of the economic transition, and the nature and timing of specific measures. As a result, it was not until May 24, 1990, that a government economic strategy, reflecting the above principles, was officially adopted as a formal resolution.

The June 8-9 parliamentary elections brought about major personnel changes in the federal parliament, with the broadly based Civic Forum and Public Against Violence together winning 170 of the 300 total seats, the Communist party retaining only 47 seats and the Christian Democratic Alliance capturing 40 seats. Less-extensive personnel turnover took place in the executive branch, since many of the ministers of the transitional government belonged to the newly formed coalition of the Civic Forum, Public Against Violence, and the Christian Democrats. The new government in principle adopted the May 24 economic resolution but, apart from the elimination of a negative turnover tax on July 9, 1990, no significant economic measures were adopted in the immediate postelection period.

The main reasons for delaying the reform were the inability to achieve consensus on a specific economic program within the executive branch of the federal government, the desire of the newly elected parliament to play a major role in shaping economic laws

and policies, the need to create a completely new legal framework for economic activity,³ and the onset of difficult negotiations about the relative powers and jurisdictions of the federal and the two national (Czech and Slovak) governments.

On September 1, 1990, the government formally submitted to the parliament a "scenario of economic reform." The document contained the first detailed set of economic and social principles, specific measures, and time parameters. It was also a political document that reflected the major compromises that were speedily concluded within the relatively short period. On the macroeconomic front, the scenario placed top priority on a strict anti-inflationary policy, with all other macroeconomic goals (growth, employment, and balance of payments) being "within reasonable limits" subordinate. Specific measures that were to ensure the success of this strategy in 1990 were a zero growth of money supply and a budget surplus of at least 1–1.5 percent.⁴ Measures proposed for 1991 were more far reaching and included a restrictive monetary policy, a 2–2.5 percent budget surplus, a convertible Crown (Kcs), and a positive real interest rate.

The proposed micro policies stressed the need to induce efficient allocation of resources, introduce new institutions, and minimize the social costs of transition. The main measures identified in this context were 1) a major tax reform emphasizing value-added tax, a personal income tax, and an "enterprise" tax; 2) a budgetary reform stressing independence of units and transparency of budgetary allocations; 3) a process of de-etatization and privatization of property; 4) price liberalization; 5) internal convertibility of the Kcs; 6) reduction and

retraining of redundant labor; 7) legalization of collective bargaining and a stiff tax on wage growth; 8) restructuring of social security and health care systems and their gradual separation from the state budget; and 9) structural (industrial) policy based on Czechoslovakia's comparative advantage.

The proposed measures varied in terms of specificity, consistency, and timing. The tax reform proposal, for instance, listed a detailed set of taxes but, despite the fact that the government was elected for only 2 years, scheduled the implementation of the tax reform over a period of 3 years. The backbone of the tax proposal, the value-added tax, was to be phased in only in 1993.

The proposed privatization package consisted of a rapid auctioning of small properties such as restaurants and workshops, speedy restitution of certain types of properties confiscated by the previous government, and a somewhat slower commercialization and privatization of medium-sized and large firms. The privatization of medium-sized and large firms would rely on a variety of methods, including investment vouchers (to be used by citizens to buy shares of enterprises), preferential sale of shares to employees, sales of shares or entire firms to foreign investors, and leasing of firms. The backbone of the proposed microeconomic program was the liberalization of prices that was to take place for a significant part of commodities on January 1, 1991. In this realm the proposal was both emphatic and cautious, noting the need for various forms of price regulation and the need to link price liberalization with the opening of the economy to imports. The principle of internal convertibility obliged enterprises to sell their foreign exchange to the banks, but promised unrestricted possibilities to buy foreign exchange for international transactions.

The variety of views among the architects of the scenario could be perhaps best gauged by comparing the economic and social sections of the document. In contrast to the subordinate position given to income growth, employment, and social security in the restrictive package of economic mea-

³An alternative would have been to adopt temporarily a modified set of Western (for example, German or EEC) laws. However, in view of the voluminous nature of Western legal statutes and the paucity of skilled translators, it turned out to be simpler to create a new set of Czechoslovak laws.

⁴These goals were in fact pursued from the start of 1990.

asures, the social program stressed the social and ecological orientation of the upcoming market economy and placed priority on social justice, employment, workers' incomes, and social security. It declared significant decline of real incomes to be unacceptable and called for an *ex ante* social agreement on the acceptable limit. This aspect was largely brought in line with the more austere economic part of the reform package by the end of 1990.

The parliament approved the scenario, but, from the standpoint of implementation, the striking feature was the large number of laws and decrees that were to be drafted and passed before the major parts of the reform would be launched on January 1, 1991. This indeed proved to be a major burden and the resulting fatigue was increasingly visible. The introduction of some widely expected measures (for example, the privatization of small enterprises) has consequently been delayed.

III. Economic Developments in 1989 and 1990

As shown in Table 1, the 1989 slowdown in NMP growth turned into a decline in 1990. Employment also decreased, but in a less pronounced way. In many cases the labor force reduction has taken the form of retirements and termination of guest workers.

Despite the commitment to a restrictive monetary policy, various measures pointed to a relatively fast expansion of money supply in the first half of 1990, followed by a decline in the last quarter. Consumer prices rose significantly, reflecting both the increased money supply and the rising velocity of circulation of money. Nominal wages rose slower than inflation, but real consumption continued to increase in the first half of the year. Personal savings have registered a significant shift into foreign exchange accounts. The runs on stores that took place in the last quarter of 1990 suggest that consumers have intensified attempts to reduce their savings and money balances in the expectation of higher inflation.

The point of major uncertainty is the enterprise sector. The fall in production, profits, and trade with CMEA countries all reflect the vulnerability of enterprises to the disintegration of the CMEA market. Indeed, after falling 9 percent in 1989, real exports to the Soviet Union declined additional 15 percent in the first half of 1990.⁵ The concomitant drop in the Soviet deliveries of oil and raw materials resulted in a

⁵By the end of 1990, many enterprises were still unable to conclude the usual annual trade contracts with their Soviet partners. Moreover, those that did were unsure whether the contracts would be honored.

14 percent decline in Czechoslovak imports from the USSR in the first half of 1990. Exports to developed Western countries rose by about 7 percent in real terms, but imports from this area jumped by more than 21 percent from January to June, 1990.

A major problem is enterprise insolvency—it has been rapidly rising. This phenomenon is particularly severe because many government subsidies to enterprises were in the past extended in the form of revolving credits. The current pursuit of tight monetary and fiscal policy has resulted in a major increase in interest rates and requests for rapid repayments of enterprise loans by banks. Enterprises have been caught off guard, as the bank interest rate on short-term loans has recently exceeded 20 percent, and they are increasingly relying on inter-enterprise credit.

Finally, the October devaluation of the Kcs/\$ commercial exchange rate from 16 to 24 has created considerable difficulties for nonexporting firms. Similarly, the 10 percent revaluation of the Kcs vis-à-vis the ruble in the first quarter of 1990 created financial difficulties for enterprises with a heavy export orientation toward the Soviet market. Most enterprises expect to continue operating on this market and have not made significant steps toward diversification or restructuring of operations.

IV. Prospects

At the end of 1990, the official government forecast for 1991 predicted a 5 percent decline in real GNP, a 30 percent rise in the consumer price index, unemployment of 5–7 percent, and a \$2.5 billion increase in foreign debt. The extent to which this forecast will materialize naturally depends on a number of factors.

The short-term economic situation will be significantly affected by key external developments such as the political and economic situation in the Soviet Union and the world price of oil. If extreme, these developments could temporarily swamp the impact of internal systemic and policy changes. In particular, a major disintegration of the Soviet

economic activity, resulting in a decline of paid orders for Czechoslovak goods or of deliveries of Soviet oil, would result in a major shock to the Czechoslovak economy. Of course, certain shock is expected in any case as on January 1, 1991, Czechoslovakia starts conducting its trade with the Soviet Union in convertible currencies and at world prices. This shift results in a significant deterioration in the terms of trade for Czechoslovakia.

On the internal side, the major danger lies in further delays of the reform and in the introduction of an inconsistent package of measures. As the major reform steps are approaching, there appears to be rising discontent, a decrease in credibility and increasing resistance to a significant (albeit temporary) fall in living standards. Further delays would probably solidify the opposition to undertaking a major and rapid economic transformation. Similarly, if the government were to abandon the overall program and enact only a set of partial and inconsistent measures, the resulting disequilibria could engender significant opposition to further reforms. Examples of possible mishaps include the loss of macroeconomic stability, a major rise in inflation in the presence of rigid wage controls, an inability to spur the development of small and medium-sized (private sector) enterprises as major layoffs take place in state-owned firms, undertaking only partial price liberalization, and enforcing the foreign exchange surrender without giving enterprises the possibility to obtain hard currency on demand. These and other partial measures have backfired in other countries, and there is no reason to expect Czechoslovakia to fare differently.

There is also considerable room for optimism. Czechoslovakia is one of the few reforming economies that enjoys relative financial stability, a low level of foreign debt, a solid human capital base, and low wages. The economic program has been relatively carefully prepared and could yield rapid results. Recent investments by foreign companies (for example, Volkswagen and Glaverbell) into Czechoslovak enterprises

Economic Development in Yugoslavia in 1990 and Prospects for the Future

By JANEZ PRASNIKAR AND ZIVKO PREGL*

In this paper, we evaluate the performance of the Yugoslav economy within the framework of reforms currently taking place in other socialist countries. We first present the stream of events leading up to 1990, followed by the development of events in the year 1990, and then discuss the possible scenarios of further development, considering the present situation in Yugoslavia.

I. Economic Performance During the 1980's

A. *The Zig-Zag Economic Policy*

Yugoslavia reached high rates of economic growth during the 1970's.¹ This was achieved primarily on account of large external debt. The growth of the external debt at the end of the 1970's therefore demanded decisive steps to correct economic policy.

During the first period that was the phase of curtailing of domestic demand and stimulating exports (from 1982 to 1984: III) (see V. Bole and M. Gaspari, 1991), economic policy concentrated on reducing domestic demand and stimulating sales to markets abroad (i.e., export promotion, exchange rate adjustment). This was attempted by using a host of restrictive measures including wage and price controls, limits on public energy usage, and controls on investment. This policy had a number of significant consequences: there was no significant increase in the inflation rate, the trade and current

accounts were improved, and domestic demand declined. Nevertheless, the policy had a negligible effect on relative prices since it was based on restrictive measures (a stop-and-go policy).

The subsequent period was the period of policy slackness (1985–86), that nullified the results attained during the first period. This policy attempted to stimulate economic output in the hope that an increase in productivity would bring about economic stability. In order to achieve this goal, an expansionary monetary policy was put in place, interest rates were pegged (with the real interest rate, in effect, negative), and the exchange rate was fixed to an artificially high level that stimulated imports. Predictably, the result of this policy was a rise in the inflation rate.

The third period was the period of full indexation (1987–89) when a new accounting technique was put in place. This encouraged economic entities to adopt a nominal indexation of economic categories. The change in input prices affected only the inflation rate, and had no effect on relative prices.

A comparison of the three periods reveals the vacillating (zig-zag) decisions made by economic policymakers. Shock therapy (active policy measures concerning the exchange rate and interest rates, freezing of wages, and a restrictive monetary policy) is usually followed by a period of increased demand that essentially nullifies the initial results, and will again be followed by a period of economic shock.

This comparison shows that the long-term stagflation in the Yugoslav economy was not a result of misguided economic policies, but of the consequences these policies had on economic performance (see Table 1). The source of this failure is the present economic system and its structural disproportions that are inherent in all socialist coun-

¹The average rate of growth in GNP was 7.0 percent for 1963–73 and 5.6 percent for 1974–80. The rates were similar to those achieved by similar countries in the world (middle income oil importers). See Jozse Mencinger (1989).

tries.² Another contributing factor may be the pronounced differences in the development of different regions within Yugoslavia.³ Many arguments have been presented in support of the thesis that it is not possible to achieve long-term stability in the Yugoslav economy merely with macroeconomic policy measures. For macroeconomic policy to be effective, it is necessary to fundamentally change the present economic system.

B. From High Inflation to Hyperinflation in 1989

The realization that fundamental changes were necessary in the economic system resulted in the implementation of the "Three Nominal Anchors" program, introduced in 1988.⁴ The new government was established

²For example, Ivan Ribnikar (1989) states that social ownership is the main cause of the continuing economic problems.

³The difference in GNP between two of the country's regions, Slovenia and Kosovo, increased from 5:1 in 1955 to 7:1 in 1983 (see Mencinger).

⁴The essentials of the program, jointly established with the Yugoslav government and the IMF, were to restrict the growth in nominal wages, loans, and public spending. However, within 1½ months, the restrictions on loans were already rescinded, and by the end of 1988, restrictions on wages followed a similar route.

in March 1989, and decided first to implement institutions based on principles of market economies. They later attempted to stabilize the economy by implementation of shock therapy. The government directed the economy by liberalizing prices, wages, imports, and personal foreign currency accounts, which together would bring about equilibrium of relative prices. In addition, it deregulated the corporate sector, enabling economic entities to operate more autonomously. Finally, the government embarked on a policy of diminishing the budgetary burden on the economy.

Prior to the enactment of any of the stabilization policies, inflation in Yugoslavia had continued on its own rapid course. As mentioned, the new cycle of price increases caused a phenomenal adaptation in the accounting system in 1987. This necessitated a full indexation of all nominal monetary figures. Unfortunately, this practice was not suitable for effective enactment of macroeconomic policy (see Bole and Gaspari). In 1987–88, escalating prices particularly encouraged budget deficits, financed through the help of monetary authorities. The deregulation of wages in 1989 and the policy of accommodating exchange rates resulted in an uncontrollable dance of adjusting prices, wages, and exchange rates, and, of course, heightening inflationary expectations. Without formal institutions to ensure the proper collection of taxes and the resulting problems in financing the budget (the Tanzi effect), and because of the losses of the central and commercial banks, a large number of economic units sought to ensure their continuing income through the help of inflation. Demand for currency also increased during 1988–89, because the demand by enterprises and households increased in real terms. This increased demand for real balances made the printing of money uncontrollable. By the end of 1989, inflation in the Yugoslav economy turned into full-fledged hyperinflation. However, the deregulation of the economy contributed to growth of exports and to increased foreign currency deposits in Yugoslav banks, which directly increased foreign reserves.

II. The Economic Reform of 1990

A. The Program of Economic Reform

Observing that the prior deregulation of the economy was already yielding some desirable results, and that the situation at the end of 1989 required strong measures, in the middle of December 1989, the government prepared "The Program of Economic Reform and its Execution of 1990." The proposed program to curtail the inflation rate (the program of "Four Nominal Anchors") rested on the foundation that the main reason for the inflation was the excessive amount of money in circulation, a result of the central bank's role in the budgetary process. By linking the exchange rate of the dinar (after the denomination of the dinar to 1:10,000) to the value of the deutsche mark (7 dinars for 1 DM) and the resulting internal convertibility of the dinar, the program provided an effective disincentive to the excessive printing of money. Wages were temporarily frozen while most prices were still allowed to adjust freely (around 85 percent of them) and imports were liberalized (about 90 percent of all goods). Simultaneously, the value of the dinar indirectly appreciated in the trade with Eastern European countries, since the central bank stopped its practice of financing the annual surplus by printing money.

In addition, the following measures were also proposed. 1) The National Bank of Yugoslavia should restrict its practice of lending to certain sectors (the federal budget, agriculture, exports) and instead become an independent professional institution whose primary purpose is the control of monetary aggregates. Losses resulting from exchange rate inequities should be covered solely by fiscal (budget) expenditures. 2) Fiscal policy should play a more active role in the stabilization of the economy and should assume the responsibilities that would be abandoned by the central bank under the first measure. 3) The country should continue to reschedule its foreign debt and continue to negotiate the terms of payment with its creditors.

B. Implementation of the Economic Reform of 1990

The program to halt inflation began to take effect by the end of December 1989. The results are evident from Table 2. The data shows a radical reduction in the rate of inflation in the first half of 1990. The monthly inflation rate (64.3 percent in December 1989) was reduced to virtually zero in April and May. It was in these months that full internal convertibility of the dinar was established. Foreign currency reserves actually increased by \$3 billion during the first half of 1990 because of an influx of foreign currency (caused by workers' remittances and the time needed for enterprises to bring foreign currency into the country was shortened) and because citizens traded in their foreign currency for the new, more stable, dinar.

However, during the first 6 months of the year, it was evident that certain goals were not obtained. 1) Wages increased at a monthly rate of 5.5 percent. Economic policy did not succeed in stopping wage increases as predicted. 2) Public spending was not decreased, since resource allocation was still adapted to the conditions of hyperin-

flation and, in large measure, depended on changes in wages. 3) Reform of the banking system did not proceed as anticipated due to problems with the revision of bank balance sheets and difficulties in parliamentary procedures. Interest rates for short-term loans (40–50 percent) constitute a substantial pressure on prices. 4) Industrial production decreased by 10 percent during the first half of 1990 (compared with the first half of 1989). 5) Inflation was still relatively high during the first 3 months of 1990 and increased the real exchange rate of the dinar, thus jeopardizing the export-oriented part of the Yugoslav economy.

These negative trends continued into the second half of 1990, despite the introduction of the second phase of reform.⁵ Inflation in the economy is once again approaching dangerous levels. One reason for this is increasing wages and public spending. Income in the public sector rose by 44 percent in September 1990 in real terms, compared to the same period in 1989. Output is generally decreasing at a slower rate than in the first 6 months of the year, but unemployment is accelerating. The economic decline is also evident in international trade and in the balance of trade. The trade deficit for the first 9 months of 1990 was already \$2.415 billion. By the end of August, foreign currency reserves had grown to \$10.1 billion. However, depositors withdrew 10 percent of their foreign currency savings in October. Depositors had obviously lowered their expectations about the prospects of success for the current reforms.

In large measure, these negative trends were attributable to the reforms themselves. Monetary authorities had abandoned their restrictive monetary policies during the summer months. Financial institutions again actively provided insecure loans, short-term loans to cash-starved enterprises, and advances to bureaus of exchange during July and August. This return to undisciplined activity was inadvertently made possible

through policy measures enacted by the government. In its efforts to stop declining output, the government had eliminated some restrictions on monetary policy that brought about this new wave of undisciplined financial activity. Another contributing factor was increases in wages for government employees that resulted in wage increases throughout the economy. While the increases for government employees were granted in compensation for a virtual freeze in government wages that had been in effect the first 6 months, the public did not look upon these wage increases favorably.

These economic policy measures (increase in selective loans to agriculture, increases in wages at federal institutions, balancing of the budget) along with a growth in the level of wages, increased overall public spending, and the return to financial irresponsibility significantly damaged a recovering economy. This damage, when coupled with the inevitable return to restrictive monetary policy, portends an even larger recession. In addition, a number of external factors also hindered the reform process, including the Persian Gulf crisis (\$1.3 billion in 1990), a drought in a main agricultural area of the country (\$1.6 billion), and heightened centrifugal forces resulting from neglect of federal laws and the practice by some autonomous provinces in establishing their own policies on prices, wages, and fiscal activities.

III. Possible Scenarios for the Future

Any predictions about the future economic developments in Yugoslavia are dependent on political and nationalist questions. Rather than speculate on the outcome of the tense nationalist situation, we can only present the options that seem most likely to us at the present.

The first scenario is that the government believes that democratic processes will continue to spread across all of Yugoslavia. It also believes a democratic environment will permit a successful reimplementation of the reform program. The second scenario is that of the federal presidency, which has forced

⁵The new legislation more courageously promotes ownership and restructuring of the banking system, and discourages monopolies.

the republics to make a decision on whether they would prefer a confederate Yugoslavia or a federation similar to the present state. Finally, some republics are working toward independence, in the belief that they can more successfully enact a stabilization program on their own than in the union. Because Yugoslavia is a country in transition politically as well as economically, all of these options are legitimate and possible.

Although it is impossible to predict which option will eventually be realized, it is clear that any of these options could lead Yugoslavia on a path toward political pluralism, a market-oriented economy, and thereby create an environment in which a consistent economic policy can be successful. Of course, policies that do not result in

these outcomes will not be acceptable to most Yugoslavs and to the international community.

The Economic Integration of Post-Wall Germany

By IRWIN L. COLLIER, JR. AND HORST SIEBERT*

It would be hard to devise a better controlled experiment for comparing different economic systems than the experience provided by East Germany and West Germany: two nations that formerly were one, occupied by people of the same background, the same culture, and the same genetic inheritance, torn apart by the accident of war. On one side of the Berlin Wall is a relatively free economic system; on the other side, a collectivist society.

[Milton Friedman, in W. Breit and R. W. Spencer, 1986, p. 89]

Modern experimental economics cannot duplicate experiments of the scale or the duration of postwar Germany. Now post-wall Germany offers a fascinating follow-up experiment to test the economic integration of an ex-centrally planned economy into a larger, established market system. In this paper we examine the experiment that began with the monetary, economic, and social union (MESU) of East and West Germany in July 1990.

The MESU treaty was signed on May 18, 1990. Two bold strokes resolved the issues of the institutional framework for economic integration and macroeconomic stability. The economic order of the FRG was transplanted to the GDR and East German fiscal and monetary sovereignty was transferred to West Germany in advance of the political act of German unification.

Two processes will determine the size of the post-wall integration dividend. The first process is the privatization of the East German economy—the assignment of private rights to existing East German assets. The second process involves real economic adjustments, including adjustments by existing

firms and the creation of a broad base of new small and midsize businesses. The gains from integration arise from merging a large open economy, relatively well-endowed in capital and technology, with a smaller, semi-autarkic economy, relatively well-endowed in labor and land. While the long-run prospects for Germany look excellent, problems encountered in the privatization and the adjustment processes make it unlikely that the integration of the post-wall German economies will be quick and easy.

I. Initial Conditions and Long-Run Prospects

According to Western estimates of relative real consumption based upon detailed consumer price comparisons and expenditure data for both East and West Germany, real consumption expenditure by East German working families was only about half the West German level (Collier, 1989). Because of higher labor force participation rates, longer work weeks, and shorter vacations in the GDR, average East German living standards were much less than half the West German level during the last half of the 1980's. The ecological gap between East and West Germany was at least as wide.

Aggregate investment in East Germany dropped sharply during the first half of the 1980's, and one could sense a steady deterioration of East Germany's infrastructure and housing stock over the past decade. There were clear indications that planned investment was inadequate to sustained planned growth of output (Collier, 1987).

Looking beyond the crumbling buildings, obsolete equipment, and desolate state of the environment, the long-run prospects for East Germany are bright. Within 4 or 5 years, we expect to see major progress in living standards and productivity as well as effort at ecological recovery. The contributing factors for this rapid growth scenario

*Department of Economics, University of Houston, Houston TX 77204, and Kiel Institute of World Economics, Duesternbrooker Weg 120, P. O. Box 4309, D-2300 Kiel 1, FRG, respectively.

may be identified as 1) the economic integration effect, 2) the capital accumulation effect, and 3) the impact of the market economy on economic behavior.

Economic integration of East and West Germany will exploit differences in factor endowments. West Germany contributes abundant capital and technology whereas East Germany brings a dowry of well-trained (though not necessarily cheap) labor and land. Thus, there will be gains from increased specialization as the new states open themselves more than ever before to exploit trading opportunities with West Germany and the rest of the world. The inability of East German industrial products to compete successfully in international markets in the past was largely due to insufficient specialization in production that limited economies of scale and to a lack of innovation. Furthermore, almost all East German producers were at the mercy of single domestic or CMEA suppliers for critical materials and components. Finally, the regional structure of East German foreign trade, especially its extremely large share of trade with CMEA partners, reflected political constraints rather than economic logic.

The capital accumulation effect is the positive association of high rates of growth with high rates of capital accumulation for economies that start from relatively low endowments of capital per capita. The capital stock East Germany brought into united Germany is largely economically and ecologically obsolete. Almost 55 percent of industrial equipment was installed over one decade ago, compared to about 30 percent in West Germany. This is somewhat comparable to the situation of the West German economy in 1948 when high rates of capital accumulation were necessary to rebuild a war-damaged capital stock, and to equip a labor force that had grown by approximately twelve million eastern refugees (Siebert, 1990).

The final reason for the favorable long-run prospects of the new states of the FRG was demonstrated in the controlled experiment mentioned at the beginning of this paper: economic system matters a great deal for economic performance. Following the eco-

nomic and monetary reform of 1948, industrial production increased in the Bizone (British and American zones) at an annual rate of 50 percent within 5 months. From the second half of 1949 through the end of 1951, real GNP grew at 17 percent annually in West Germany. Were history to repeat itself, the new federal states could make up for much lost time by 1995.

One must resist the temptation to overstate common patterns between West Germany in 1948 and East Germany in 1990. The most important difference between the two starting points is that East German firms entered German MESU as inefficient producers. The adjustment to the market economy in the new federal states entails a J-curve with a substantial drop in production and elimination of unnecessary jobs. In November, there were 589,000 unemployed—an unemployment rate of only 6.7 percent. But a far more accurate reflection of idle labor resources and a forecast of 1991 unemployment in East Germany is found in the 1.77 million workers on short time.

The wage-setting process is also different now from 1948. The wage level in East Germany at the start of economic integration is completely out of line with productivity, and wages are likely to grow even faster than productivity. Without an exchange rate to depreciate that would increase the competitiveness of East German firms, the wage rate should have taken over the function of giving East Germany a temporary comparative advantage in labor-intensive industries. However, as workers continue to move to higher paying jobs in the West and unions in East Germany (with the support of unions in the West) continue to push for wage increases to close the East/West wage gap, cheap labor will be only a fleeting advantage that the new states possess for attracting investment.

The social union, that went into effect simultaneously with the monetary and economic union in July extended a social welfare system that has evolved to fit a relatively rich, well-proportioned economy to cover a much poorer economy in the middle of significant real adjustments in the transition from central planning to a market sys-

tem. Direct investment in existing firms that require large cuts in the workforce will be discouraged because the dismissal constraints represent significant entry costs.

II. Problems of Transition—Reorganization and Privatization

The core of the adjustment process is the restructuring of East German industry. In the restructuring of existing firms, three different aspects need to be distinguished: legal independence of the constituent enterprises in the large industrial trusts (Kombinate); economic efficiency of the individual enterprises; and ownership.

Most of East Germany's production (1988) was organized into 316 Kombinate, of which 221 were vertically and horizontally integrated industrial Kombinate. The Kombinate were protected from domestic competitors by governmental market delimitation, while an extreme policy of planned specialization within CMEA protected the Kombinate from foreign competitors as well. The first stage of reorganization was completed when all the constituent firms of the Kombinate (approximately 8,000) were declared legally independent economic units by law.

Now subject to formidable competitive pressures, East German firms must increase their efficiency by restructuring their input and product mixes: the production of inputs in-house that are cheaper to buy from other firms will be discontinued; departments dedicated to prolonging the life of economically obsolete capital will be shut down; product lines motivated by political considerations will be abandoned; and the provision of social services such as kindergartens will be eliminated. Cutting back the workforce is clearly the most sensitive issue facing managers. Through the end of June 1991, managers have the option of keeping people on the payroll as short-time workers with a large part of the difference in earnings paid by the government. This is the reason why industrial production has fallen by half without a corresponding jump in unemployment.

The organizational restructuring of East German firms is closely linked to the issue

of privatization. The rights to publicly owned firms were transferred to a new government trustee agency, the Treuhandanstalt. The primary task of the Treuhand is to privatize East German firms. The Treuhand has a secondary task that is to restructure industry, and if the net value of assets (i.e., privatization receipts less costs of restructuring) is positive, to transfer the net receipts from privatization to either the governments or the people of the new federal states. Thus the legislative intent was that the Treuhand should only exist for the time necessary to accomplish these tasks. However, there is a genuine risk that the Treuhand might evolve into a super "machinery" of sectoral policy exposed to strong political pressures.

Should the Treuhand restructure firms before offering them to private buyers or sell each firm "as is" and let new owners do the restructuring? This has been the subject of considerable public debate in Germany, and apparently within the Treuhand as well. The restructure-first approach has been rightly criticized on Hayekian grounds that the Treuhand has insufficient information for selecting winners from losers for the allocation of scarce resources generated by the Treuhand's borrowing, or from revenue generated in earlier privatizations. The Treuhand has also met with severe criticism for not proceeding faster with privatization. In 1990, Treuhand sales amounted to only about 2.5 billion DM.

The reorganization of existing firms is just one aspect of the restructuring of the East German economy. An important task of restructuring is to encourage the creation of new and small firms. New firms are needed to absorb the employees laid off as inefficient firms cut employment or shut down altogether. The distribution of firms in manufacturing by number of employees in the GDR in 1987 was characterized by a relatively small share of firms with fewer than 100 employees (4.4 vs. 35.9 percent in the FRG).

Over 226,00 new businesses have been established in the first 10 months of 1990. About half of the new businesses are in retail trade and restaurants. Strengthening this growing *Mittelstand* will be the former owners (or their heirs) of small reprivatized

enterprises. About one-fourth of the 12,000 small firms previously nationalized have been transferred back to the original owners.

German economic integration constitutes a Schumpeterian "event" or a "new frontier" in the sense of Alvin Hansen. Vast quantities of investment will be needed to get restructured firms started and to create new jobs. While a strong boom in West German investment is underway, nothing comparable can be seen in the East as of yet.

The German MESU treaty was drafted with two primary goals in mind. First, it was hoped that the introduction of the DM would check the out-migration of East German labor by changing expectations of future living standards in the East. After dropping to a net out-migration of 12,000 per month in May and June, the flow increases to 30,000 per month during July through September. Second, by transplanting West German economic law, the treaty gave investors a legal environment for investment identical to that in West Germany, at least in principle. The May 18 treaty was supposed to signal the start of the great capital race into East Germany. However, with the notable exception of West German financial institutions and retailers, both West German and foreign investors have stayed pretty close to their starting blocks.¹ Their caution is not ill-founded.

Uncertainty in titles to land. Returning land titles to original owners sounds like a simple and obvious way to reestablish property rights in land. However, the passage of time has complicated matters considerably, and public records of land ownership turn out to have been badly neglected in East Germany. Establishing title to any particular property can be quite difficult, especially at a time when millions of people want to check these public records simultaneously! There is a pressing need for some form of title insurance in East Germany now.

¹The five leading German economics research institutes estimated in October that 5 billion DM of direct investment would flow into the East German economy during 1990 and that another 15 billion DM would follow in 1991.

The infrastructure bottleneck. The run-down public capital stock of roads, railways, airports, and telecommunications is wholly inadequate for the rapid development of the new federal states. There are two issues in widening the infrastructure bottleneck: how fast can the East German infrastructure be expanded and how will the expansion be financed? Lags in supplying public infrastructure investment can be both long and variable—Germany is no exception. Considering the time factor alone, there is a strong argument for privately financing as much infrastructure investment as possible. The argument is considerably strengthened by the prospect of huge future government budget deficits.

Space for new businesses. This is an infrastructural bottleneck that has major consequences for the rate of new job creation. New firms must be able to acquire office space, warehouse space, and locations for setting up production facilities. New industrial and office parks as well as shopping centers are sorely needed.

III. Macroeconomic Aspects of German Unification

The united German economy is divided into an economic boom in the West and an enormous contraction of economic activity in the East. The West German economy is growing faster than it has in nearly 15 years. Real GNP in the West has grown 4.6 percent in 1990 with 2.5 percent real growth forecast for 1991. In comparison, industrial production in the new federal states has plummeted—from August to October 1990, it had fallen 51 percent below the monthly levels of the previous year.

Ex ante, it should have been obvious that German economic unification would initially constitute a strong negative shock to the aggregate demand for East German goods and a positive shock to the aggregate demand for West German goods. East Germany went from a position of semi-autarky to one of complete opening to West Germany and all of West Germany's trading partners, and the average quality of East German products was far below the western standard. Without subsidies for many of the

products exported to Western markets (Pentacon cameras, for example), there was no reason to expect the initial impact of unification to increase East German "exports" to West Germany much, if at all. In fact, compared to one year earlier, September deliveries to East Germany had increased by 277 percent, while the flow of goods from East Germany only increased by 36 percent (*Handelsblatt*, November 26, 1990).

Despite the collapse of production in the new federal states, the economic and social union of East and West Germany has increased the disposable income of East German households. Unfortunately for East German producers, Western products have been getting a large share of that spending. Purchases by East German consumers contributed between one-half to a full percent of the real GNP growth in the *old* federal states in 1990, and are expected to account for another 0.5 percent of the growth in 1991.

The expected combined budget deficit in 1991 for all German federal, state, and local governments (including social insurance funds), on a national accounting basis, has been forecast by the Kiel Institute of World Economics at 130 billion DM. Estimates of the 1991 deficit of 150 billion DM (5.4 percent of GNP) are now reported in the financial press. Relative deficits of this size were last experienced in 1975 and 1982 when the government budget deficits were 5.7 and 4.1 percent of GNP, respectively.

Ideally, progress on deficit reduction over the next several years will come primarily from spending cuts, nontax sources of revenue (for example, private financing of infrastructure in the East and the privatization of government assets in the West) and economic growth in the new federal states.

The five leading West German economics research institutes estimate potential cuts in the defense budget of 5–6 billion DM and 10 billion DM in personnel and nonpersonnel expenditures, respectively (from a total defense budget of 55 billion DM). There are approximately 130 billion DM of government subsidies, including hidden tax breaks, that could be pruned back for sav-

ings of 20–30 billion DM annually. Privatization of a part of the telecommunications sector controlled by the Bundespost or of other federally owned firms such as Lufthansa is being considered as another possible source for deficit reduction.

Over the past decade, West Berlin has cost West German taxpayers about 20 billion DM annually. Between 1951 and 1990, the support for Berlin and the zone-border regions plus miscellaneous "costs of division," such as the payments for East German political prisoners, totalled over 400 billion DM, 85 percent of which went to West Berlin (*Handelsblatt*, November 12, 1990).

IV. The Political Economy of German Economic Integration

We close by reminding the reader of an obvious difference between 1948 and 1990—1948 is part of the historical experience shared in the united Germany of 1990. Erhard's success inspired the self-confidence of West German policymakers last spring as they pushed for a swift and radical break from the institutions of the centrally planned economy in East Germany.

In the East, we observe an understandable though unrealistic expectation that West German levels of real consumption can be achieved without closing the productivity gap between East and West. East German impatience for West German prosperity has been enhanced by an entitlement mentality that has survived the economic system that fostered it. These psychological factors still have the potential to complicate both the privatization and real adjustment processes of German economic integration. If in response to political demands, government intervention comes to dominate market adjustments during economic integration, structural change in the new federal states could likely repeat West Germany's experience with sectoral policy for declining industries on a much larger scale. The risk of the new federal states turning into a Mezzogiorno is genuine.

Will the new united German polity allow the market a chance to prove itself once

again? The economic question for Germany in the 1990's will be whether the German federal government can step back from playing the lead role in German integration now that the institutional foundations have been completed (pending successful privatization), and play only a supporting role in rebuilding East Germany's infrastructure and environment. In 1991, the Treuhand will no longer guarantee credit for working capital and most of the short-time workers will make the statistical transition to the ranks of the unemployed. Headlines will be dominated by news of plant closings and soaring unemployment. The demand for government action will be difficult to resist. German policymakers will need steady nerves and stamina if the benefits from the windfall of German economic integration are not to be squandered.

CHINESE ECONOMIC REFORMS, 1979-89: LESSONS FOR THE FUTURE[†]

Chinese Enterprise Behavior Under the Reforms

By ROGER H. GORDON AND WEI LI*

During the recent decade of economic reforms from 1979 to 1989, the Chinese government adopted a series of policy and institutional changes aimed at increasing the productivity of the economy. While the initial efforts focused on agriculture, the government also tried to improve the performance of the nonagricultural sectors. Prior to the reforms, these sectors were heavily dominated by state-owned firms operating under central planning. The reforms decentralized many decisions to the firm level, or at least to the local government level. By 1985 most firms, for example, could change output quantity and variety, production technology, and the timing of production. To improve incentives, firms were allowed to retain a much larger fraction of profits. While the central planning apparatus remained in place, planned inputs and outputs became increasingly small fractions of the total inputs and outputs of firms. In principle they should not have affected marginal incentives. Outside-of-plan inputs and outputs could be traded freely among firms. While prices for goods allocated through the plan were tightly controlled,

there were increasing attempts to relax control over the prices at which trade took place outside of the plan. This type of dual-pricing system directly imitated the structure of the "responsibility system," which had proved so successful in agriculture.

Little attempt was made, however, to introduce factor markets in the state-enterprise sector. Even at the end of the period, firms continued to complain about being compelled to employ excess workers and workers could not quit without permission, though firms were given the discretion to hire temporary workers under contract. While the People's Construction Bank was set up to handle credit for new capital investment, proposed projects still needed to be approved at some level of government, and in practice investment decisions continued to be made primarily by the government planning ministries or by local governments.

Another key aspect of the economic reforms was to make it easier for local governments, collectives, and even private households to set up their own firms outside of the state planning structure. There was rapid growth in the number and output of such firms in response to the new flexibility. For example, the output of township firms grew dramatically from 8.6 percent of national nonagricultural output in 1979 to 26.6 percent in 1988. (See State Statistics Bureau, 1989, pp. 44; 248.)

The objective of this paper is to examine more closely the incentives created by these reforms, in order to better understand the causes of their success and failure. We start by discussing the state-owned sector, then examine the private and collective sectors.

Some of the results reported in this paper come from a survey of 403 Chinese state enterprises conducted as part of a joint research project with the Chinese Academy of Social Sciences, funded by the Ford Foundation.

I. State-Owned Enterprises

Prior to the economic reforms, managers of state-owned enterprises in China were rewarded primarily based on their success in meeting physical output targets set by the government. With the reforms, rewards were instead based much more heavily on the firms' tax payments and accounting profits. While the tax rate on firms remained high by Western standards, in practice more than three-quarters of retained profits went to the firms' managers and workers. The link between accounting profits and manager/employee compensation might if anything have been stronger than in Western firms. These strong financial incentives, along with the decentralization of decision making, in theory should have led to a sizable increase in efficiency.

The story was not quite so simple, however. Given the large differences between accounting prices and market prices, accounting profits could well provide a poor approximation to true economic profits. When existing goods prices differ from market prices and allocation decisions are decentralized, barter trade should commonly arise at implicit prices for each type of good, which together are sufficient to clear all markets. What impact does barter trade have on firms' accounting profits and marginal incentives? If underpriced output is exchanged for a combination of cash plus a sufficient amount of underpriced input, then the two errors in the accounts should just offset, leaving pretax accounting profits unaffected. However, firms often sell underpriced output for underpriced consumer goods, or even for under-the-table cash payments. According to the evidence reported in our 1990 paper, sellers appear not to report receiving these extra payments, while buyers do report making them. The most compelling evidence was that firms reported that the inflation rate in the output price of machinery and industrial materials was very low, consistent with sales at official prices, whereas firms reported that the prices they paid when buying machinery and industrial materials grew at a rate roughly approximat-

ing the inflation rate in market prices. Since the responsibility for auditing a firm's accounts often rests with the firm itself, this evasion should not be surprising. This tax evasion increases the fraction of economic profits retained by the firm, reinforcing the incentives to raise efficiency. The amount of such evasion increased quickly during the period as market prices grew with inflation while official prices remained relatively constant.

The resulting loss in tax revenue led the government in 1986-87 to shift to a contract system in which each firm signed a contract with the government, typically for 5 years, agreeing to minimum tax payments during each year of the contract. But firms could still evade any tax on sales and profits above that necessary to justify the minimum tax payments, and in any case the inflation rate was high enough that real tax payments continued to fall.¹

Barter trade was not possible in all markets, however. Unless barter is costless, distorted official prices lead directly to distorted incentives. Often these distortions were sufficiently large that the government continued to intervene, either directly ordering decisions or else offering enough cheap credit or subsidized inputs to make the decisions it desired profitable from the firm's perspective. For example, the pay structure within firms remained highly egalitarian, so not surprisingly firms reported having an excess number of unskilled workers and a shortage of skilled workers. Given this pressure, the government continued to assign workers to firms and virtually forbade layoffs.

The interest rate on bank loans was also kept far below a market-clearing level. Not only was the interest rate low, but both interest *and* principal payments were nor-

¹In a sample of 361 firms with available data (see our 1990 paper), the annual growth rates of total tax payments from 1984 to 1987 were 10.48, 3.31, 1.47, and -1.35 percent, respectively, while the official annual retail price inflation in the same years were 2.8, 8.8, 6.0, and 7.3 percent, respectively. See State Statistics Bureau, p. 689.

mally tax deductible. Allowing these deductions is equivalent to allowing expensing of debt-financed new investments for tax purposes. In theory, under expensing no tax is collected in present value on a marginal investment—the cash flow to the government is proportional to that received by the firm, so when the firm breaks even so does the government. Therefore as a result of the below-market interest rate, debt-financed investments were subsidized on net.² Demand for loans exceeded the supply of funds, and increasingly so during the period as the rising inflation rate caused the real interest rate on loans to drop. Government intervention was necessary to ration credit.

When making allocation decisions, the government could not rely on the information available in a firm's financial accounts to judge the merit of any given project. That left the government with the option either of correcting the accounts for the distortions created by mispricing, or of continuing to plan directly the desired allocation of resources. Given the importance of the distortions, most importantly in interest rates, energy prices, foreign exchange rates, and the cost of skilled workers, and the pervasive way that these distortions filtered through the entire pricing structure, correcting the financial accounts would be virtually impossible.³ It is no wonder that the government was loathe to rely on such accounting figures to determine which firms to push into bankruptcy.

In spite of the problems with the financial accounting figures, they were still used heavily in determining the allocation of new investment, if only by requiring firms to invest a given fraction of their net-of-tax accounting profits. These reinvestment requirements were not self-enforcing, how-

ever—given the high tax rates on future profits, a firm's employees should much prefer the money now to receiving a fraction of the flow of net-of-tax profits resulting from investing the money in new capital. In practice, reinvestment rates were far below the levels required by regulation.

Even basing pay on a correct measure of economic profits would still create anomalous incentives if employees do not remain with the firm throughout the period affected by any given economic decision, or if employees fear a change in the compensation rule in the future. For example, managers might have an incentive to sell off existing capital in order to generate current profits and current bonuses, hoping that by the time the future losses show up they have been promoted or retired. Western firms try to avoid these incentives by basing the compensation of managers on changes in share values rather than on current profits. Chinese officials did recognize this problem. One experimental solution, known as the Asset Management Responsibility System, involved auctioning the job of manager every 5 years. The departing manager would receive a bonus based on the bid price of the new manager, thereby tying his compensation to the future prospects of the firm.

What happened in response to all these policy changes? In our earlier paper, we found in a sample of 403 state-owned enterprises that total factor productivity in the sample grew between 1983 and 1987 at a rate of 4 percent per year, while real output grew on average at 8 percent per year. Thus, decentralized decision making, even with badly distorted incentives, raised productivity in the state sector.

II. The Private and Collective Sector

The planning system in China, similar to that in the Soviet Union, favored heavy industry and highly capital-intensive technologies, resulting in a very different allocation of resources than is seen in market economies. For example, in 1986, 5 percent of workers were employed in the commercial trade sector in China, compared with 15 percent in Indonesia, 11 percent in Brazil,

²In fact, depreciation deductions were allowed as well, but during much of the period 40–50 percent of these deductions had to be handed over to the government, thereby mostly offsetting the gain from the tax deduction.

³See, for example, the complicated discussion in I. M. D. Little and James Mirrlees (1974) concerning how to correct appropriately for such distortions in cost-benefit analyses.

and 21 percent in the United States. (See State Statistics Bureau, p. 997.) Therefore, it should not be surprising that opening the economy to the entry of new firms would lead to rapid changes.

Private and collective enterprises responded swiftly to the economic liberalization. The former quickly expanded in the retail sector, while the latter became much more important in the industrial sector.⁴ Not only did these firms produce badly needed goods and services, but they also introduced competitive pressures into the economy, undermining the monopoly power of state-owned firms.

While the proliferation of private firms should not be surprising to Western economists, one should keep in mind that this occurred despite arbitrary taxes and erratic government interference, limiting, for example, their scope of trade, employment, and access to credit and scarce resources. Until 1985, for example, private firms could employ no more than seven workers. They also faced the risk of being shut down by the government at any point. Nonetheless, they grew and prospered.

The rapid growth of collectives, especially township enterprises, cannot be explained so simply. The local government normally controlled the access of collectives to workers, scarce inputs, and credits, and had to approve the appointment of managers, investment decisions, and even production plans. In addition, however, the local government kept most of the taxes paid by collectives in its jurisdiction,⁵ and had some control over the allocation of retained earnings. Since the local government effectively

owned and controlled these firms, and operated in competition with many other local jurisdictions, the resulting allocation decisions should have been relatively efficient. Each local government was small enough to take as given the implicit market prices for factors as well as goods—mobility across jurisdictions increased substantially during this period. The local government, by increasing efficiency, increased the resources under its control. Local government incentives remained distorted, however, to the degree to which some of the taxes paid by collectives had to be transferred to higher levels of government. In contrast, the national government's allocation decisions for state-owned firms would not be so constrained by market pressures. Thus, decentralization, even within the government, brought increased prosperity to the economy.

These improved incentives required decentralizing both control of tax revenue and control of the operations of firms to the same level of government. This was done not only for collectives but also for many smaller state-owned firms, implying the same improvement in incentives. Occasionally, however, control of the operations of larger state-owned firms was also delegated to local governments even though the bulk of the tax revenue went to the national government. The high national tax rates on these firms discouraged local investment in them, particularly when they were competing against locally owned firms whose tax revenue stayed within the jurisdiction.

Due to local taxes and distorted prices, locally controlled firms themselves faced different incentives than the local governments. As a result, local governments felt compelled to intervene regularly. This intervention often took the form of restrictions on trade with other jurisdictions. For example, when the implicit market price for a good exceeded the local opportunity cost of producing it, then the local government had an incentive to force local firms to buy the locally produced good, even if its price exceeded the implicit market price. Similarly, when the consumer price of a good exceeded its implicit market price, the local

⁴The market share of retail sales by private enterprises rose from 0.24 percent in 1979 to 17.8 percent in 1988, while the share of industrial output of the collectives rose from 21.53 percent in 1979 to 36.38 percent in 1988. See State Statistics Bureau, pp. 601; 267.

⁵Under the fiscal system adopted in 1985, all profit taxes from locally controlled firms including all collectives and some state firms go to the local government treasury, while other tax payments, such as the product tax and the value-added tax, were still shared with the national government.

government had an incentive to prevent outside firms and individuals from selling directly to local consumers, to keep the profits from the price differential within the community.

III. Lessons for the Future

The shift towards decentralized decision making during the reform period in China resulted in a rapid increase in output and in productivity. Yet in spite of these successes, the economic situation was very bleak by the end of the reform period. The problems arose mainly from the growing inflation rate. Official prices did not keep up with inflation, resulting in increasing price distortions and growing opportunities for tax evasion. The right to buy at official prices became increasingly valuable, resulting in growing corruption and growing rent-seeking behav-

ior, which undermined political support for the reforms. In addition, the increasing distortions to the measure of financial profits made oversight by the government of firm behavior, and even of the behavior of the economy as a whole, more and more tenuous.

Why Has Economic Reform Led to Inflation?

By BARRY NAUGHTON*

In China, as in other former command economies, inflation has threatened the economic reform process. Does inflation inevitably accompany the transition from command economic systems? Why did China (long regarded as the most successful example of gradualist reform) stumble into a severe inflationary episode at the end of the 1980's? This paper examines the Chinese experience of inflation, stressing the importance of fiscal imbalances.¹

The transition from a command to a market economy requires extensive change in the price system and in relative prices. In the command economy, prices were relatively unimportant in individual resource allocation decisions. Prices shaped some household consumption decisions, but most production and investment decisions were made by the government without reference to relative prices or profitability. Prices were fixed for long periods of time, and price relationships were highly distorted. The transition to a market economy requires that prices approach scarcity values, and play the dominant role in allocating resources in production and investment as well as consumption. Extensive changes in relative prices will inevitably be a part of an economic reform process, but must this lead to inflation?

The Chinese record, examined in Section I, shows that during the first 8 years of the reform process (1979–86), increases in the level of consumer prices were caused primarily by changes in relative prices. Food prices, long set at artificially low levels, were allowed to rise, and this accounted for most of the increase in the overall price level.

Beginning in 1987, however, prices of all important consumer goods began to increase, and inflation accelerated. Pure price level increases (the monetary component of price changes) became quantitatively more important than changes in relative prices. It was after this steadily worsening outbreak of inflation that tough deflationary policies were adopted that halted inflation, but also slowed growth and undermined reform (see my 1990 article).

Why did a period of moderate increases in the overall price level combined with substantial realignment of consumer prices give way to a period of pure inflation? To answer this question we must first reconsider the change in the function of the price system during the transition from a command economy. In the command economy, prices did not play a primary role in resource allocation, but the price system did serve as the primary instrument of resource mobilization. Government controlled prices were structured to create high prices and profitability for modern industry, at the cost of correspondingly low prices in agriculture, mining, and most services. This highly distorted price structure ensured that the bulk of national saving occurred in the state-owned modern industrial sector, the financial surpluses of which were then drawn into the government budget. Besides funding normal government services, the budget accounted for the bulk of national investment. Thus, investment was not guided by price signals; instead, the resources for government investment were provided by the overall price structure. Product price controls substituted for a taxation system, facilitating a large and intrusive government sector.

Clearly, if the price system is to serve its new function as the primary determinant of resource allocation, it must also shed its previous function as the primary instrument of resource mobilization. A single instrument cannot adequately perform two dif-

*University of California-San Diego, IR/PS, La Jolla, CA 92093.

¹This paper makes extensive use of official Chinese data, reprocessed into categories consistent with Western economic analysis. An appendix providing details of data sources and manipulation is available from the author on request.

ferent functions. As prices approach scarcity values during an economic reform process (and in particular as intersectoral price differentials diminish), macroeconomic stability requires either the creation of a new taxation system to fund government revenues, or the shrinkage of government outlays as revenues decline. If neither of these occur, or if they occur too slowly, government deficits will create inflationary pressures, the magnitude of which will depend on the way deficits are financed. Section II below documents the huge changes that have occurred in the role of the Chinese government budget during reforms. Overwhelmingly dependence on modern industry for revenues has characterized the budget throughout, but relative price changes in the economy have sharply reduced the profitability of modern industry. The result has been a huge decline in the share of budget revenues in GNP, a chronic fiscal crisis, and large overall public sector borrowing requirements. This has created a source of inflationary pressure separate from that created by the direct effect of relative price changes.

Fiscal deficits and price realignments cause inflation only if the banking system provides sufficient liquidity to accommodate price increases. Section III shows that monetary policy shifted to an extremely accommodative stance at the end of 1984. This shift was the final element that caused the gradual buildup and explosion of inflation in 1988. Inflationary pressures were temporarily contained by running a large deficit on international payments, but subsequently the deficit was narrowed while credit policy remained slack, and open inflation increased. This shift in monetary policy can be associated with the need to finance government investment through the banking system.

Section IV summarizes the argument. China initiated a process of price realignment without carrying out complementary reforms of the tax and fiscal system. As a result, budgetary revenues declined rapidly, eventually exceeding the point where government officials were willing to cut control over real resources correspondingly. They then turned to the banking system to gain

access to financial resources, accommodating the budget deficit and causing inflation. This suggests that inflation in China was not inevitable, but rather was the result of flaws in the sequencing of economic reforms.

I

Since the initiation of reforms, consumer prices have increased sharply on three occasions: 1980, 1985, and 1988. On each of these occasions, inflation was led by increasing food prices. Table 1 shows annual increases in the consumer price index, non-staple foods, and the slowest-growing component of consumer prices. While the price of staple grains has remained heavily controlled and subsidized, consumer prices of other food products have increased rapidly. State food prices have been raised, and consumers purchase an increasing portion of food on the free market. In each of these three episodes, food price increases were initiated by raising state prices and compensating urban workers with wage increases. In each case, after the initial inflationary surge, inflation moderated, and some food prices actually declined briefly. Thus, while changes in relative prices caused inflationary pressures, the government was initially able to contain those pressures.

Note: Col. (1) = Urban CPI; Col. (2) = Nonstaple foods; Col. (3) = The component of urban consumption outlays with the lowest inflation rate.

In addition to the episodes of food price adjustment, there are two distinct periods in the changing price level. Overall inflation rates were much higher between 1985 and 1989 than previously. During the 1978-84 period, food price increases were partially offset by reductions in the price of manufactured consumer goods, shown in column 3 of Table 1. Beginning in 1985, the overall price level began to increase at a substantially faster pace. Nevertheless, for 2 years, food price increases continued to be the major component of consumer price inflation, and this was the period of maximum price realignment. Beginning in 1987, increases in the overall price level became more important. Finally, during the third quarter of 1988, accelerating inflation and an announcement of imminent further price reforms led to panic buying and hoarding. This pushed inflation rates temporarily up to annual rates above 50 percent during July and August.

In the 1978-86 period, increased prices of nonstaple and miscellaneous foods, making up 40 percent of urban household outlays, accounted for 78 percent of the total increase in the price level; during 1986-89, they accounted for only 28 percent of the total increase in the price level. Explaining Chinese inflation requires that this shift between two substantially different regimes be explained.

II

Before economic reform, modern industry carried out the vast majority of national financial saving. In 1978, modern industry accounted for 12 percent of the labor force, but it generated a net financial surplus (total profits plus taxes collected from enterprises) equal to 25.4 percent of GNP, accounting for nearly four-fifths of national financial saving. Moreover, only small sums were retained by the enterprises, so virtually all of this, 24.7 percent of GNP, was remitted to the fiscal authorities. Household financial saving was small, amounting to only 1.3 percent of GNP, and households paid virtually no direct taxes. Thus the modern industrial sector, predominantly state owned, was

the dominant source both of national saving and of fiscal revenues.

The extraordinarily prominent role of modern industry in economywide financial balances was the result of the peculiar price structure discussed above. Low state-set agricultural procurement prices were most important, but low interest and depreciation charges were also significant. In order to maintain profitability differentials, substantial barriers to entry were erected around industry. Economic reform substantially altered price relationships, through three channels: 1) Agricultural procurement prices were raised relative to industrial prices, redistributing income to rural residents. Although increased prices of staple grains were absorbed by government subsidies, price increases of other foods and agricultural raw materials were passed through to urban residents and processing enterprises. 2) Depreciation charges and interest rates were increased. 3) Barriers to entry in the manufacturing sector were lowered, and industrial production by rural cooperatives and individuals, as well as local governments operating off-budget, exploded. Rapid entry into the most profitable manufacturing sectors exerted downward pressure on prices and substantially lowered profitability in industry overall.

As a result, financial surpluses in modern industry have declined drastically and steadily as a proportion of GNP since 1978. By 1988, total profit and tax of modern industry had declined to 16.7 percent of GNP, of which 3 percent of GNP was now retained by the enterprises, and 2 percent used to repay bank loans. Thus, industrial remittances to the budget declined from 24.7 to 11.6 percent of GNP, or by 13.1 percentage points. Budgetary revenues also declined drastically and steadily, by an amount almost exactly equal to the decline in industrial remittances. Between 1978 and 1988, budgetary revenues, appropriately adjusted and including all subsidies, declined from 35.4 to 19.8 percent of GNP, or 15.6 percentage points. Eighty-four percent of the decline in budgetary revenues is attributable to declining remittances from modern industry. There are few examples of

a nation's budgetary share declining by such a huge amount in such a short time (Mario Blejer and George Szapary, 1990).

It is worth emphasizing that the decline in the financial surplus of modern industry is not due either to slow growth of industry or to declining efficiency in the industrial sector. Industrial output has grown substantially more rapidly than GNP, and the proportion of the labor force in modern industry has increased to 15 percent of the total. The best efforts to measure total factor productivity in state industry, after correcting for price changes, shows significant increases through the period under consideration (Kuan Chen et al., 1988). Thus, the decline in profitability seems to be entirely attributable to the impact of changing relative prices, initiated by increased agricultural procurement prices and intensified by the downward pressure on relative manufacturing prices created by lowered barriers to entry.

To cope with the huge reduction in budgetary revenues, the Chinese government slashed expenditures, and the overt budgetary deficit has remained modest. Budgetary outlays declined from 35.4 percent of GNP in 1978 to 22.1 percent in 1988, yielding a budgetary deficit of 2.3 percent of GNP in 1988. The reduction in budgetary expenditure was accomplished by dramatic reductions in military expenditures and investment outlays. Government subsidies of all kinds (predominantly food grain) grew initially, to 7–8 percent of GNP, but as prices of nonstaple foods were raised, subsidies were stabilized at 6 percent of GNP. Yet these changes in the budget do not fully display the impact of the government on the economy. Budgetary financing of fixed investment declined sharply, but the central government investment plan did not decline in corresponding fashion. Completed investment under the central plan equaled 9 percent of GNP in 1978, but after initial reductions, recovered to 8 percent of GNP during the late 1980's. Taking into account the need to finance all stages of the investment process, less than half of the central investment plan was funded by budgetary revenues. The central government needed to borrow about 5 percent of GNP in order to

finance its investment plan. If we take the central government investment plan as a measure of the real use of investment resources mandated by the central government, the total government borrowing requirements is equal to the sum of the budgetary deficit and the deficit in the central investment plan, amounting to a total of 7 percent of GNP in 1988. A total deficit of this magnitude puts significant pressure on macroeconomic balance: beginning in 1987, total government borrowing requirements exceeded 50 percent of total credit creation by the banking system.

III

Changes in the structure of national saving have caused changes in the nature of the banking system and credit policy. Household saving has exploded, and annual household accumulation of monetary assets has surpassed 8 percent of GNP annually since 1984. As household saving has increased, the banking system has increasingly played the intermediary role common in most countries. Unlike the prereform pattern, the bank now channels saving from the household sector to businesses (still primarily state owned). Increased household saving made it possible to finance large public sector deficits under certain conditions.

Overall, credit policy has shifted sharply during different periods. Total lending grew between 1978 and 1983 at a 13 percent annual rate. From 1984, credit creation accelerated, and the rate of increase was sustained at 26 percent annually through 1987. This dramatic shift in credit policy immediately put upward pressure on prices, but these were dampened in 1985 by a trade deficit of 5 percent of GNP. Moreover, the output response was vigorous and industrial production grew rapidly. In subsequent years, though, as the trade deficit was gradually eliminated (by mid-1988), and inflationary expectations became rooted, the continuing expansionary credit policy led to an acceleration of inflation.

The abrupt shift to an expansionary credit policy contrasts with the gradual increase in total central government borrowing requirements. As central government requirements

increased in the mid-1980's, they threatened to crowd out the new decentralized investments that were fueling China's economic growth. At this point, the government, unwilling either to reduce its own borrowing or to crowd out decentralized investment, instead shifted to a much more expansionary credit policy. This shift was the proximate cause of inflation.

IV

The stylized facts presented above can be fully explained by two fundamental characteristics of the Chinese reform process. First, substantial progress was made in liberalizing product prices and introducing market forces into the economy. In particular, lower entry barriers in industry generated explosive growth in small-scale and rural output. Second, conversely, virtually no progress was made in rationalizing financial relationships, restructuring the tax system, and clarifying ownership rights and obligations for use of assets. The lack of a modernized tax system meant that changes in relative prices introduced in the wake of reforms caused a substantial erosion in government fiscal revenues. This might not be bad if the government were to acquiesce in a reduction of its control of resources. However, as the Chinese leadership sought to maintain a large central government investment program, they ordered the banking system to provide financing, and this led to the inflationary credit policy that ultimately disrupted the economy and the economic reform process.

This analysis suggests there is no inevitable reason why a gradual reform process must lead to severe inflation. Adjustment of relative prices does cause "spikes" of short-term inflation, but these can be managed if fiscal and monetary policy are sound. Instead, the cause of inflation is found in the sequencing of Chinese reform measures. If the Chinese government had carried out tax reform at an earlier stage of reforms, and broadened the tax base beyond the industrial sector, they might have been able to avoid the inflation of the 1980's. Gradualist reform strategies thus require early enactment of fiscal restructuring, but

there is nothing in the macroeconomic record that suggests the gradualist approach is inherently flawed.

Differences in economic system and level of development may limit the applicability of these lessons to European socialist countries. Having carried out economic reforms since 1978, China has a larger flex-price sector than any European command economy, with market prices existing alongside plan prices for nearly all commodities. Moreover, China's reforms achieved early success in agriculture, so that rapid growth of food output reduced the difficulty of price adjustment. Evidence of suppressed inflationary pressures is much greater in European command economies, especially the Soviet Union, than in China, where inflationary pressures can be openly expressed in free markets parallel to state controlled markets (but see Richard Portes and Anita Santorum, 1987). On the other side, the European socialist countries have greater administrative capabilities and, since 1989, fewer ideological constraints than China. As a result, they will certainly adopt reform strategies less gradual than that of China in the 1980's. However, all the socialist countries face difficult choices about the sequence and pacing of reforms, and the Chinese experience provides valuable information about the benefits and pitfalls of a gradualist approach.

Economic Reform of the Distribution Sector in China

By RICHARD H. HOLTON AND TERRY SICULAR*

Economic reform in China, slowed after the Tianamen Square incident in 1989, may be resuming. The Chinese Academy of Social Sciences has been asked by the central government to suggest further economic reforms in the distribution sector. Here we discuss this topic, noting first the role of distribution in the economic development process, then the changes in China's goods distribution process since economic reform was instituted. We conclude with observations about an ideal distribution system for China.

I. Distribution in the Process of Economic Development

The role of goods distribution in furthering economic development has received scant attention.¹ Yet distribution is clearly part of the production process when the latter is viewed in its entirety. As goods move from the producer to the final buyer through the channels of distribution, a variety of services must be performed ("produced") if final buyer demand is to be satisfied. Marketing textbooks note that the channels of distribution create form, time, place, and possession utilities; the channels provide information flows in both directions; assembling, grading, packaging, financing, risk taking, and negotiation are other components of the marketing process (Philip Kotler, 1980).

Improvements in technology, management, or organization can reduce the cost of production of distribution services, just as innovation in production can reduce the

cost of producing the physical good itself. Technological and managerial changes that reduce distribution costs affect the supply function for the product faced by final buyers. Assuming perfect competition at all levels, cost-reducing innovations in distribution will shift the supply function in the final buyers' market to the right, reducing the equilibrium price paid by end-users.

In an open economy, improvements in distribution might permit exports where none were possible before, even if the cost of producing the physical product were to remain unchanged. Thus a latent comparative advantage might be converted to an operative one.

It follows that increased efficiency in goods distribution can accelerate economic development just as can increased efficiency in the production of the goods themselves. Distribution might even be considered a candidate for a leading sector in the economic development process, that is, incremental investments in distribution might yield a higher net social return than investments in other sectors. Investment in distribution may also be a key during the economic transformation of socialist economies. Its importance is evident in the USSR, where inefficiency in the distribution system has caused food shortages even in years of bumper harvests.

II. Goods Distribution in China: An Overview

Before 1979, goods distribution in China was marked by much inefficiency. The physical infrastructure was primitive, units were overstaffed, inventories of unwanted goods accumulated, high-quality goods were scarce, and waste was palpable. Most consumer goods moved either through the Supply and Marketing Cooperatives or through the wholesale and retail system under the jurisdiction of the Ministry of Commerce. Grain was sold by the collectives or individ-

¹ Unless otherwise noted, the term "distribution" herein will refer to the distribution of goods in the economy, not to income distribution.

ual growers to procurement stands under the Bureau (or Ministry) of Grain.² Capital equipment and other industrial products typically moved directly from producer to final buyer according to the dictates of the planning system. Planned distribution permeated the system, and the units in the system were assigned both customers and suppliers. Competition was absent.

A significant characteristic of the planning system was regional protectionism. Municipal authorities required the local department store to buy from the local wholesale company, for example, which in turn bought from local factories. Supplies from elsewhere were brought in only as a last resort, even though comparable quality goods might be available at lower prices (Bei Tao and Holton, 1989).

Since 1979, economic reforms have shattered the vertical, closed commercial system and allowed diverse channels to develop. Three aspects of these reforms are noteworthy. First, private individuals, collectives, producers, and government units outside the Ministry of Commerce can now buy and sell more freely. Second, the vast majority of small-scale, state-owned commercial enterprises have been converted to private or collective ownership, and efforts are being made to convert the rural supply and marketing cooperatives (that had in fact been state operated) to true cooperatives. Larger units in the state commercial system, while still state-owned, have been established as companies separate from the administrative bureaucracy. They are now managed under responsibility-system contracts that allow them to retain some profits, and they have more freedom to buy and sell as they wish. Third, the scope of planning has been greatly reduced, so that by the mid-1980's only a small number of commodities were subject to planned allocation at planned prices. By 1988 only half of China's retail sales took place at state-set prices (Almanac of China's Prices Editorial Committee, 1989, p. 351).

²At times this agency was an independent ministry; it is currently under the Ministry of Commerce.

A. Distribution of TV Sets

China's production of TV sets has exploded; the 1988 output, almost 25 million sets, was more than 50 times that of 1978 (State Statistical Bureau, 1990, p. 455). In 1985 there were 154 TV set producers in China, compared with 60 in 1978 (State Statistical Bureau, 1988, p. 251). Many of the new factories were set up by provincial and local governments outside the traditional production centers. Thus Shanghai, Beijing, and Tianjin, which in 1978 had produced 68 percent of China's TV sets, produced only 31 percent in 1987. (See State Council Office of the Leadership Group...1986, p. 249; State Statistical Bureau DITMS, 1988, p. 230.)

Prior to the reforms, the wholesale distribution of TV sets was monopolized by what are now the Metals, Transport, Electrical and Chemical Companies (MTECCs) under the Ministry of Commerce.³ The MTECCs purchased TV sets from factories and sold them to designated retailers. TV sets were in short supply and could only be purchased with ration coupons. State planning governed the quantities distributed and prices paid.

The MTECCs no longer dominate the distribution of TV sets. Manufacturers can now sell directly to consumers, as can private businesses, collectives and government departments outside the Ministry of Commerce. Furthermore the MTECCs at different levels and in different localities are no longer constrained and can compete with one another.⁴

The government continues to plan the production, distribution, and prices of TV sets, but the rapid growth in production has reduced the role of planning. Rationing has

³These companies handle distribution of bicycles and motorcycles, electrical appliances, small metal products such as hand tools, and household chemical products such as paint and cosmetics.

⁴Indeed, the employees of the Chengdu Municipal MTECC, formerly under the Sichuan Province MTECC, boasted that they outsell their former superior organization. (Interviews, Chengdu Municipal MTECC, July, 1990.)

been abandoned, and prices of black and white TV sets have been set free. For color TV sets, the price bureaus set retail prices and retail and wholesale margins. State-owned retail stores typically honor the planned retail prices, but private retailers frequently do not. Both state and private wholesalers often ignore the planned margins. During the panic buying of 1987–88 when market prices for TV sets rose rapidly, factories could earn higher profits by selling directly to consumers. They therefore refused to sell at the low planned factory prices. The state commercial sector, which continued to sell at planned retail prices, suffered.⁵

Early in 1989, the central government attempted to regain control of TV set distribution and to slow price increases by permitting TV sets to be sold only by agents with special permits. This shrank private wholesaling activity, but competition among the government departments responsible for issuing permits led to the overissue of permits, and so price increases continued.⁶

The demand for TV sets fell in 1989 and producers resumed selling at the planned factory price, but higher-quality models, still in short supply, continued to be sold directly by manufacturers at market prices. To sustain factories in the face of weaker demand, the MTECCs were required to buy certain quantities of TV sets at the planned prices. Yet the MTECCs and state retail stores were prohibited from stimulating sales by reducing prices, so inventories accumulated; the carrying costs reduced the MTECCs' profits. The MTECCs and state retailers have expanded advertising, extended warranties, and offered free gifts to buyers. Some have violated the regulations and reduced retail prices.

B. Grain Distribution

Since the 1950's, the Chinese government has tried to assure the urban sector of ade-

quate grain at low and stable prices. The rural population was expected to produce grain sufficient to supply its own needs and also to deliver planned quantities to the state at low prices. The margins between these planned purchase prices and the selling prices were small or negative, and so the government lost money on grain distribution. Interprovincial trade was small, averaging only 1.1 percent of domestic production in the late 1970's (Nicholas Lardy, 1990). Farm households and collectives could store and process grain for their own consumption, but the Grain Bureau had a virtual monopoly on grain marketing, storage and processing; private distribution of grain was minimal.⁷

Reforms since 1977 have freed grain trade considerably. Farmers can trade grain on free markets once they have fulfilled their delivery quotas; individuals can transport grain across county and provincial borders; state-owned units outside the Grain Bureau can trade and process grain. Retail grain markets have emerged, as have wholesale markets at traditional transshipment points such as Wuxi, Wuhu, and Shashi (Lardy). Planned grain procurement has been reduced and by 1989 only 70 percent of the grain marketed by farmers was sold to the Grain Bureau. And about half of the Grain Bureau purchases were at market-based "negotiated" prices. Thus by 1989 more than half of the grain marketed moved at market or market-based prices (Almanac of China's Commerce Editorial Committee, 1988, 1990; State Statistical Bureau, 1990).

This picture, however, probably exaggerates the development of freer markets for grain. "Negotiated" prices in some circumstances are set administratively and do not follow market trends. In urban areas, grain marketing is dominated by state units distributing at planned, ration prices, and the free market, serving only a limited demand, is sensitive to the planned price. In major grain-producing areas for rice (in the South), wheat (North), and corn (North and North-

⁵Interviews with MTECCs, retailers and producers in Sichuan and Beijing.

⁶Interviews, Chengdu and Chongqing, July, 1990.

⁷For a detailed discussion of prereform grain distribution, see Sicilar (1988).

west), the government dominates and strictly controls local marketing of the major grain. To assure that quotas will be filled, free markets are closed during procurement season and interregional trade is prohibited. When market trade is permitted, local governments often enforce price ceilings or influence the market price through their own market operations. In the case of rice, the central government has reimposed the Grain Bureau's monopoly; individuals and units outside the Grain Bureau cannot supply rice.

Competition among government units, common in the distribution of TV sets, is very limited in the case of grain and is discouraged by the authorities. For example, in the late 1980's, Guangdong reduced its planned grain distribution and allowed farmers to specialize in commercial crops. To procure grain, Guangdong's grain agencies bought in neighboring provinces. This raised prices in these provinces, and caused their grain agencies difficulties in enforcing quotas. Their complaints led the central government to prohibit Guangdong from buying grain in neighboring provinces.

Losses on grain distribution discourage competition among government units. The planned retail price is lower than the planned procurement price, and the central government reimburses the grain departments for only a portion of the resulting losses. Hence agents under the Grain Bureau have little incentive to seek new sources of grain or customers for grain. This situation motivates local governments to prohibit outsiders from coming in to buy grain; the outside demand would drive up the local price, put upward pressure on the government's prices, and make it more difficult to enforce quotas.

Competition from individuals and units outside the Grain Bureau is also limited. Producers can now market their grain themselves, but they are unable to mount a serious challenge to the state distribution system. Producers are numerous and small, with limited access to credit and long-distance transportation. The monopoly power of the Grain Bureau, however, is limited because farmers can resist selling to the

Grain Bureau when the terms are too unfavorable.

III. Conclusions

What features would characterize an "ideal" distribution system for China, and how can China move closer to such a system? One with perfect competition at all levels, from producers through the channels of distribution to final buyers, is clearly impossible. All the competitors at the wholesale or the retail level cannot have identical locations, so their offerings will be differentiated in at least this one dimension. Furthermore one can ask whether perfect competition is in fact desirable. In retailing, for example, consumers presumably want some variety in the products and services offered and so should be willing to pay slightly higher prices in order to enjoy that variety. Thus some degree of monopolistic competition may be consistent with the maximization of economic welfare (F. M. Scherer, 1980, p. 24).

This suggests that the ideal distribution system would be characterized by monopolistic competition, with large numbers of agents, some product and service differentiation, free entry, and no excess profits. But in many areas in China, markets are thin and thus oligopoly conditions are likely to apply to much wholesale and retail trade if the units are to be of an efficient size. One option would be simply to let the free market work and to tolerate the resulting quasi-monopoly profits. These profits might be held in check if competition or the threat of entry were enhanced by improving transportation and providing buyers with good information about prices in adjacent markets.

An alternative approach would be to recognize that many enterprises in distribution are natural monopolies and hence should be regulated as are public utilities in the United States. Restricted entry would permit each unit to operate at a point approximating the least cost rate of output. Price controls would apply. The prereform system in China approximated this model, except that the units were government operated.

As noted earlier, the government-owned and regulated approach to the design of the distribution system has not been considered satisfactory in China.

For some products the current dual pricing system could be a compromise solution, that is, part of the output is sold at the state plan price and the remainder at market prices or at prices approximating the free market. But if planned and market prices differ, illegal arbitrage and rent-seeking behavior emerge. Producers find excuses for not delivering the planned output at the state price, since sales at market prices are more profitable. Moreover, as the experience with TV sets and grain demonstrates, the dual price system tends to break down. For any particular product, either the plan is effectively eroded by the market, or the government's efforts to enforce the plan limit the marketing channel and prevent it from operating efficiently.

A second and perhaps superior compromise policy would let the free market operate, but for certain products the government might impose price ceilings or floors. In effect this would limit the economic rents earned by quasi monopolists in distribution. Thus the government could limit the monopsony power of grain merchants in rural localities by setting a minimum price to be paid to farmers. At the retail level monopoly rents on basic necessities could be limited by mandatory price ceilings.

One could argue that this policy at the retail level would not be effective because the quasi monopolist, prohibited from charging a profit-maximizing price for a basic food item, for example, would simply charge more for other products in the product mix. But presumably the profit-maximizing merchant is already pricing each product at a point where marginal cost equals marginal revenue; the profit-maximizing price on item A would not be affected by the price charged for item B. A second objection is that price ceilings and floors can be difficult and costly to maintain. Successful cases do exist, however; witness the Indonesian price policy for rice (C. Peter Timmer, 1989).

Developments in the distribution of TV sets and grain in China suggest the condi-

tions likely to promote movement toward the ideal distribution system. Success is more likely when 1) some players exist who are powerful enough to challenge the state distribution system, 2) agencies within the state distribution system have incentives to compete among themselves, and 3) production is growing rapidly.

In the case of TV sets, producers were in a position to challenge the local MTECCs because any one locality generally contained a single, relatively large TV set manufacturer. This producer had access to bank credit, trucks, and other resources needed for marketing. Since TV set producers generated revenues for the local government (local governments taxed the profits of the local manufacturing units) and were usually closely linked with a local government bureau, they also had political bargaining power. Such conditions did not hold for grain producers.

TV set distribution has also been characterized by competition among branches and departments under the Ministry of Commerce. This competition has arisen because, following managerial reforms establishing them as profit-earning companies separate from the Ministry's administrative bureaucracy, these agencies have realized that they can earn profits from competitive behavior. Departments under the Grain Bureau, however, earn small or negative profits from handling grain and hence are not motivated to handle more.

Finally, rapid growth in the production of TV sets has caused TV set distribution to outgrow government planning. Once a surplus of TV sets emerged in the late 1980's, government efforts to contain competition eased. In the case of grain, output grew rapidly in the early 1980's and surpluses emerged temporarily in 1983-84. At that time the government proposed reforms substantially liberalizing grain distribution, but these proposals were largely abandoned when output fell in 1985 and stagnated thereafter (see Sicular, 1990). Persisting fear of grain shortages has since hindered further reforms in grain distribution.

These considerations imply that simply allowing private trade and competition to emerge will not necessarily lead the econ-

omy toward the ideal distribution system. Progress toward the ideal system is likely to differ among markets and, since government commercial departments will try to maintain their dominance, depends critically on price and management reforms that encourage such agencies to compete among themselves. Meanwhile, improvements in information and transportation will lower barriers to entry and promote a more efficient distribution system.

Shareholder Heterogeneity: Evidence and Implications

By LAURIE SIMON BAGWELL*

The perfect market paradigm provides a powerful foundation for financial theory. In perfect capital markets, there are no transaction costs, all traders have equal and costless access to information, and traders act as price takers. If existing claims "span" the state space, excess supply curves are perfectly elastic. Moreover, differences in preferences or beliefs do not result in disagreement among shareholders about firm policies. Underlying this unanimity is the shared valuation of the stock, which translates into agreement about firm strategies. The ability to transact without affecting the market price is central to many important propositions, including the Modigliani-Miller irrelevance theorems.

This paper examines the nature of supply curves for corporate equity. Until recently there has been little direct empirical assessment of their elasticity. At issue is whether or not the supposition of shareholder homogeneity of valuations (and its implications) represents a good approximation to actual markets. This paper's call for further empirical evaluation of shareholder valuations echoes the perspective offered by Eugene Fama and Merton Miller, who in discussing perfect markets observed that

[N]o such market exists in the real world, nor could it. Rather, what we have here is an idealization...permit[ing] us to focus more sharply on a

limited number of aspects of the problem and usually greatly facilitat[ing] both the derivation and statement of the sought-for empirical generalizations. In the nature of the case, however, the generalizations so obtained can never be anything more than approximations to the real phenomena that they are supposed to represent. The question is whether, considered as approximations, they are close enough; and this, of course, is a question that can only be answered empirically and in light of the specific uses to which the approximations are put.

[1972, pp. 21-22]

This paper provides evidence that current shareholders' valuations differ *dramatically*. This provocative empirical finding implies that the hypothesis of common valuations indeed is not always a good approximation. If the approximation is poor, then conclusions stemming from it must be reconsidered. This requires additional analysis of the microeconomic foundations of disagreement in shareholder valuations, and the contexts where shareholder disagreement is substantial.

I. Evidence: Supply Curve Elasticity

My earlier paper (1990a), investigating the extent to which the supply curves for equity deviate from perfect elasticity, examines shareholder tendering responses in Dutch auction repurchases of stock. In Dutch auctions, the company states the number of shares it will repurchase, and a price range within which stockholders can offer to sell their shares. Shareholders fill out tendering schedules indicating how many shares they are willing to sell at each price within this range. It is a dominant strategy for atomistic

shareholders to tender their shares at their true valuations.

The firm then compiles the tendering responses from the lowest to the highest price, constructing the supply curve for the stock. All stockholders who tendered at prices at or below the minimum price necessary to acquire the number of shares the company seeks receive the purchase price for their tendered shares. In the sample examined, on average, 16.7 percent of the outstanding shares are tendered at or below the purchase price, which is at a 13.4 percent premium above the preannouncement market price.

Firms are not required to disclose the shareholder tendering responses. However, 32 of the 52 firms conducting Dutch auctions between 1981 and 1988 disclosed this proprietary information to me. The individual tendering responses provide a unique opportunity to examine directly the elasticity of the supply curve for stock.

The supply curves documented in Dutch auction repurchases have a distinct upward slope. When bids are ranked from lowest to highest, the average difference between the 1st and 6th percentile bid is 4.4 percent of the preannouncement market price, from the 6th to 11th is 2.6 percent, and from the 11th to 16th is 2.0 percent. That is, the difference between the 16th percentile shareholder valuation and the 1st percentile shareholder valuation is 9.1 percent. The average arc elasticity of the supply curve is 1.67. Formal regression analysis confirms the significant upward slope of these curves.

Evidence consistent with upward-sloping supply curves is detected in similar transactions. M. Bradley et al. (1988) find that the premium paid in interfirm tender offers is increasing in the fraction of target shares purchased by the acquirer. David Brown and M. Ryngaert (1990) find results similar to Bradley et al.'s for fixed price repurchase tender offers.

Andrei Shleifer (1986) also provides evidence suggestive of an upward-sloping supply curve, finding that the share prices of firms added to the S&P 500 Index increase at the announcement of the inclusion. The magnitude of the price increase is positively

related to the increased buying of the shares by Index funds. Since being included does not signal any information about stock value, the findings suggest that the price increase is being driven by increased demand in the presence of an upward-sloping supply curve.

II. Supply Curve Elasticity and Information Interpretations

In light of the evidence suggestive of less than perfect elasticity for stock, I reexamine the traditional interpretations of the share price reaction to specific corporate events. In perfect capital markets, the number of shares traded in a given stock has no effect on its price. If the market is less than perfect, a large purchase (sale) of shares could inflate (depress) the price of the shares temporarily due to market illiquidity. Further, the number of shares traded can carry new information about the stock that would cause a permanent reassessment of share value. While these alternative hypotheses have been considered extensively in the existing literature, few papers have allowed for a third possibility: a large purchase (sale) of shares could inflate (depress) the price of the shares permanently due to an upward-sloping supply curve. If the excess supply curve is less than perfectly elastic, then a large purchase (sale) alters the marginal holder of stock to one with a higher (lower) reservation price.

The typical Dutch auction repurchase buys 15 percent of the outstanding shares and increases the market price at its announcement by 7.8 percent. These price increases are frequently attributed to new information. This interpretation is appropriate when the supply curve is perfectly elastic; if the supply curve is flat, only new information can change the stock price. However, attributing the price change solely to information is misleading when the supply curve is upward sloping because, in addition to any shift in the supply curve, movement along the supply curve is confounded with new information. Specifically, if we assume that the repurchase conveyed no information, an elasticity estimate of 1.67 would nevertheless imply an average price

increase of 9.1 percent, exceeding the observed announcement effect.

Myron Scholes (1972) finds a permanent negative price reaction to the sale of large blocks. Since there is a permanent price effect, he concludes that the sale signals information to other traders. Greater price changes occur if the seller is presumed to have adverse information motivating the sale. Wayne Mikkelson and M. Megan Partch (1985) reconsider block sales in light of an upward-sloping supply curve. They document a significant negative price reaction to block sales regardless of the type of seller. Further, the magnitude of the price response is positively related to the size of the offering. While this work suggests possibly important lasting supply effects, they find no relationship between the price reaction and elasticity determinants they consider. Thus, further empirical analysis is needed to determine the relative importance of the information, liquidity and supply components of the price reaction, for not only block trades but all changes in the supply or demand of shares.

III. Supply Curve Elasticity and Corporate Control

Under shareholder unanimity, the composition of a firm's shareholders, and the elaborate rules governing shareholder voting, have little impact. Under this supposition it is difficult to explain why these rules vary dramatically across firms, and why changes in these rules result in large changes in stock prices. An example of the insights gained by allowing for shareholder heterogeneity is the role it plays in the choice of cash distribution method.

Cash distributions are usually explained as ways to signal information, alter leverage, or disgorge free cash, but few theories have untangled the choice between alternative methods of distribution. One plausible explanation is that the method of distribution is influenced by its effects on the nature of the shareholder population. For example, my article (1991) argues that distributing cash through a share repurchase as opposed to dividends serves as an effective takeover deterrent in the presence of an upward-

sloping supply curve for stock. Shareholders willing to tender in a repurchase are systematically those with the lowest valuations. The repurchase therefore skews the distribution of the remaining shareholders towards a more expensive pool, raising the cost of a takeover to the acquirer. Interestingly, targets of takeover activity account for nearly half of all recent repurchases.

On the other hand, my paper with Kenneth Judd (1989) shows that dividends may be chosen even if they are tax disadvantaged relative to share repurchase, because dividends do not change the population of shareholders. This may be desirable since it maintains the current majority. Hence, while a repurchase deters a takeover by altering the shareholder population, dividends may be desirable precisely because they do not alter the population of shareholders in the absence of takeover concerns.

When shareholders have differing preferences and transactions are costly, sometimes opposed shareholders may choose to remain together within a firm, fighting over firm decisions, instead of incurring the costs of portfolio reshuffling. Since firm decisions are made in light of the conflict, shareholder nonunanimity makes corporate control decisions central. In particular, focusing on shareholder disagreement may help us evaluate the recent prevalence of supermajority requirements and other corporate charter amendments. Rene Stulz (1988) argues that supermajority rules effectively change the marginal shareholder to one requiring a higher premium, thereby benefiting shareholders while making takeovers less likely. Allowing for shareholder heterogeneity may also yield an understanding of the increased use of nontraditional takeover mechanisms like two-tiered tender offers, and the impact of legislation like that passed in Delaware in 1988, requiring that hostile takeovers be approved by 85 percent of all nonaligned shareholders.

IV. Conclusion

Despite the importance of common shareholder valuations to finance theory and practice, there is direct evidence of significant shareholder disagreement in Dutch

auction repurchases. It is vital that we learn more about the market conditions underlying shareholder heterogeneity and the contexts where they are significant.

Perhaps the most important unanswered question is: what causes the significant deviation from perfect elasticity? My paper (1990b) sheds light on this question by examining empirically the cross-sectional determinants of supply curve elasticity in Dutch auction repurchases. Preliminary findings indicate that supply curves are more elastic when institutional holdings are high, dividend yield is high, price has not varied much in the past 5 years, and the fraction bought back is large.

Supply curves may be more elastic when institutional holdings are high because institutions have small capital gains liabilities or institutional investors share consensus. Capital gains taxes induce shareholders with lower basis values to value the share more highly; many institutions are tax exempt. Further consistent with tax-induced heterogeneity, low tax bracket investors typically hold high dividend yield stocks, hence, we would observe more elastic supply curves for these stocks. Since price variability may result in increased dispersion of basis values, these supply curves would be less elastic. Many of the same variables affect the tendering rates for fixed price share repurchases in Brown and Ryngaert. These results demand further examination of nontax sources of heterogeneity, including asymmetric information and divergence of opinion.

Knowledge of the relative importance of taxes, transactions costs, or asymmetric information for shareholder disagreement affects tax reform and regulatory policies. Consider, for example, lowering the tax rate on capital gains. Since taxes on capital gains induce shareholders with different capital gains liabilities to value shares differently, decreasing the capital gains tax diminishes the disparity of liabilities across shareholders, increasing consensus. If taxation is an important source of shareholder heterogeneity, this change in policy could lead to increased agreement among investors. Similarly, if asymmetric information is an important source of shareholder heterogeneity,

then changes in regulatory policy for required disclosure of security trading may also have important implications for shareholder disagreement. These policies, though designed for taxation or regulation, might radically change the market for corporate control.

Investor Diversification and International Equity Markets

By KENNETH R. FRENCH AND JAMES M. POTERBA*

Since the fortunes of different nations do not always move together, investors can diversify their portfolios by holding assets in several countries. The benefits of international diversification have been recognized for decades. In spite of this, most investors hold nearly all of their wealth in domestic assets. In this paper we use a simple model of investor preferences and behavior to show that current portfolio patterns imply that investors in each nation expect returns in their domestic equity market to be several hundred basis points higher than returns in other markets. The lack of diversification appears to be the result of investor choices, rather than institutional constraints.

I. International Asset Ownership Patterns

Most corporate equity is held by domestic investors. The domestic ownership shares of the world's five largest stock markets are: United States, 92.2 percent; Japan, 95.7 percent; United Kingdom, 92 percent; Germany, 79 percent; and France, 89.4 percent. This information, and other data on cross-border equity transactions, can be used to estimate the international equity holdings of investors in each country. Table 1 presents crude estimates of the equity portfolio allocation for investors in the United States, United Kingdom, and Japan.¹

¹These estimates cumulate the net purchases of equity by investors in each country, with adjustments

TABLE 1—EQUITY PORTFOLIO WEIGHTS:
BRITISH, JAPANESE, U.S. INVESTORS

	Portfolio Weight			Adj. Market Value
	U.S.	Japan	U.K.	
U.S.	938	.0131	.059	\$2941.3
Japan	031	.9811	.048	1632.9
U.K.	011	.0019	.820	849.8
France	005	.0013	.032	265.4
Germany	005	.0013	.035	235.8
Canada	010	.0012	.006	233.5

Note: Estimates correspond to portfolio holdings in December, 1989. They are based on the authors' tabulations using data from the U.S. *Treasury Bulletin* and Michael Howell and Angela Cozzini (1990). Adjusted market values exclude intercorporate cross-holdings from total market value, and correspond to June 1990 values.

The estimates show little cross-border diversification for U.S. and Japanese investors. At the end of 1989, Japanese investors had only 1.9 percent of their equity in foreign stocks, while U.S. investors held 6.2 percent of their equity portfolio overseas. The British, by comparison, held 18 percent of their portfolio abroad, divided almost equally among the United States, continental Europe, and Japan.

Since the United Kingdom is a smaller share of the total world equity market than the United States or Japan, it is not surprising that its investors hold more equity outside their own borders. However, the diversification of U.K. portfolios is a recent phenomenon. At the end of 1979, U.K. pension funds, which today hold 21 percent of their assets in foreign equities, held only 6 percent of their portfolios abroad (Michael

for both stock market and exchange rate movements. Ian Cooper and Costas Kaplanis (1986) also estimate cross-border equity holdings, but their calculations are largely imputations that do not rely on country-by-country equity flows.

Howell and Angela Cozzini, 1990, p. 30). The growth of international equity investments followed Prime Minister Thatcher's relaxation of capital controls.

II. Is Incomplete Diversification Costly?

The gains from diversification depend on the correlation of returns in different equity markets. We compute real returns from the perspective of a U.S. investor, assuming the investor uses three-month forward contracts to lock in an exchange rate for the amount of his initial investment each quarter. The average pairwise correlation between quarterly returns on the equity markets in the United States, Japan, the United Kingdom, France, Germany, and Canada for the 1975–89 period is .502. This suggests that nontrivial risk reduction is available from cross-border holdings. The correlations are similar if the returns are measured in yen or pounds, and whether or not the exchange rate risk is hedged.

To measure the costs of incomplete diversification, we assume that a representative investor in each country has a constant relative-risk-aversion utility function defined over wealth, $U(W) = -e^{-\lambda W/W_0}$, and that he maximizes expected utility.² For a given set of portfolio weights w associated with a vector of mean returns μ and a covariance matrix Σ , this implies an expected utility of

$$(1) \quad E[U(w)] = -e^{-\lambda(w\mu - \lambda w'\Sigma w/2)}.$$

In this setting, optimal portfolio weights w^* satisfy

$$(2) \quad \mu = \lambda w^{*'} \Sigma.$$

With limited historical data on international equity returns, it is difficult to measure expected returns, μ , or to infer the optimal portfolio weights, w^* , with any precision. We can, however, make reasonable estimates of the covariance matrix, Σ . Under the assumption that investors put all

their wealth in the equity of the six largest stock markets, we can ask what set of expected returns, $\mu^*(w, \Sigma)$, would explain the pattern of international portfolio holdings we observe. We use equation (2) to calculate the expected returns implied by the actual portfolio holdings of U.S., Japanese, and British investors. We also compute the expected returns implied by an international "value-weighted" portfolio strategy for investors in each nation. The last column of Table 1 shows the value weights, based on market capitalization data from Morgan Stanley Capital International but with corrections for intercorporate equity holdings as in our earlier article. The adjustment reduces the importance of the Japanese and German markets.

Panel A of Table 2 shows that substantial differences in expected returns *across countries* for investors in a given nation are needed to rationalize observed portfolio holdings. In the most extreme case, British investors must expect annual returns in the U.K. market more than 500 basis points above those in the U.S. market to explain their 82 percent investment in domestic shares. This large implied differential reflects the substantially higher standard deviation of returns on the British market, relative to returns on the U.S. and Japanese markets. For U.S. investors, the annual expected return on U.S. stocks must be 250 basis points above the expected return on Japanese stocks. In contrast, for Japanese investors, the expected return on Japanese stocks must be 350 basis points above the expected return on U.S. stocks.

The difference in expectations for different investors judging the same market are also striking. Our estimates suggest that Japanese investors, for example, expect returns from Japanese stocks which are more than 300 basis points greater than the returns U.S. investors expect. There are similar differences in the expectations of foreign and domestic investors in both the U.S. and U.K. equity markets.

Although these differences in expected returns are striking, the implied alternative of equal expected returns across all markets may not be an appropriate benchmark. As

²We set $\lambda = 3$; see our 1990 paper for more detail on calibration.

TABLE 2—EXPECTED REAL RETURNS
IMPLIED BY ACTUAL PORTFOLIO HOLDINGS

	U.S.	Japan	U.K.
A. Expected Returns Needed to Justify Observed Portfolio Weights			
U.S.	5.5	3.1	4.4
Japan	3.2	6.6	3.8
U.K.	4.5	3.8	9.6
France	4.3	3.4	5.3
Germany	3.6	3.0	4.8
Canada	4.7	3.0	4.0
B. Deviation Between Implied Returns for Actual and Value-Weighted Portfolios			
U.S.	0.9	-1.5	-0.2
Japan	-1.1	2.5	-0.3
U.K.	-0.7	-1.4	4.4
France	-0.3	-1.2	0.7
Germany	-0.2	-0.8	1.0
Canada	0.5	-1.2	-0.2

Note: See text for further description of calculations.

another alternative, we estimate the expected returns that would induce investors in each country to hold an international value-weighted stock portfolio. The *difference* between the expected return vector implied by each country's actual investment pattern, and that implied by a value-weighted strategy, is shown in Panel B of Table 2. The results again suggest that investors expect domestic returns that are systematically higher than those implied by a diversified portfolio. The differences between the two sets of implied returns for U.S. and British investors, however, are rarely larger than 100 basis points. For example, U.S. investors' concentrated holdings of U.S. stocks can be explained by "optimistic" expectations of roughly 90 basis points. A similar "pessimism" of about 110 basis points is needed to justify U.S. investors' underweighting of the Japanese market. Explaining the behavior of both Japanese and British investors requires more "optimism" regarding their own markets: 250 basis points for the Japanese, and over 400 basis points in the United Kingdom.

III. Institutional and Behavioral Explanations for Underdiversification

What explains the apparent tendency for portfolio investors, particularly in the United Kingdom and Japan, to overweight their

own equity market? There are two broad explanations. First, institutional factors may reduce returns from investing abroad or they may explicitly limit investors' ability to hold foreign stocks. It is difficult, however, to identify such constraints. Institutional barriers are unlikely to explain the low level of crossborder equity investment *today*, even though capital controls substantially restricted equity flows in the 1970's. Tax burdens that are higher on foreign than domestic equity income should lead investors toward holding domestic equity. There is little difference, however, between foreign and domestic tax burdens for most investors. Although all of the nations we examine impose a dividend withholding tax on payments to foreign shareholders, typically these payments can be credited against taxes in the investors' home country.³

Transaction costs also appear unable to explain limited international diversification. The cost of trading may be lower in more liquid markets such as New York than elsewhere, but this should incline all investors toward the most liquid market, not toward their own domestic market. Since all shares must be held by someone, differences in transaction costs should be reflected in differences in expected returns. The large gross equity flows across borders also suggest that transaction costs cannot explain why investors specialize in their home markets. For the United States in 1989, gross foreign equity purchases were fifty times net purchases (see our earlier paper).

Explicit limits on cross-border investment could also affect portfolio holdings, although few of them appear to bind at present. In France, for example, a foreign investor may not hold more than 20 percent of any firm without authorization from the Ministry of Economy and Finance. In Japan, insurance companies cannot hold more than 30 percent of their assets in foreign securities. Many U.S. pension funds traditionally

³Tax-exempt investors may face a burden from such taxes, since they have no tax liability against which to claim the credit. Even for these investors, however, the tax would only reduce expected after-tax returns in foreign markets by about 50 basis points.

interpreted the "prudent man" rule as limiting their degree of international exposure.

The current level of international portfolio investment seems to be well below any institutional constraints. In the mid-1980's, for example, foreign investors were substantial net sellers of Japanese shares. Similarly, foreigners were net sellers of U.S. equities in 1988. Such reductions in international equity investments suggest that constraints on foreign holding are not binding, implying that incomplete diversification is the result of investor choices.

A second class of explanations for imperfect diversification focuses on investor behavior. One important possibility is that return expectations vary systematically across groups of investors. Robert Shiller et al. (1990) report direct evidence on this question. In early 1990, they surveyed portfolio managers in Japan and the United States. The U.S. investors expected an average return of -0.3 percent on the Dow Jones Industrial Average over the next twelve months, compared with an expected return of -9.1 percent on the Nikkei. In contrast, Japanese investors expected an average return of 12.6 percent on the Dow, and 10.8 percent on the Nikkei. While the Japanese investors were more optimistic than their U.S. counterparts with respect to both markets, they were relatively more optimistic about the Tokyo market.

The statistical uncertainties associated with estimating expected returns in equity markets makes it difficult for investors to learn that expected returns in domestic markets are not systematically higher than those abroad. The standard error of the estimated mean annual return on the U.S. stock market, based on 60 years of data, is 200 basis points. Thus, the 95 percent confidence interval for the mean return spans 800 basis points. Because it is difficult to estimate *ex ante* returns, investors may follow their own idiosyncratic investment rules with impunity.

Another important behavioral insight concerns the perception of risk in equity markets. Investors may not evaluate the risk of different investments based solely on the historical standard deviation of returns. They may impute extra "risk" to foreign

investments because they know less about foreign markets, institutions, and firms.⁴ Country-specific closed-end mutual funds, popular in the United States during the late 1980's, may overcome these fears (see Catherine Bosner-Neal et al. 1990, for a discussion).

Although the level of cross-border equity investment is low, it is growing and with time the international diversification puzzle may recede. Cross-border equity investment patterns may nevertheless provide important insights on how investors value risk and how they select portfolios. The evidence of incomplete diversification presented here is consistent with evidence from many other markets. Ronald Lease et al. (1974) show that in the late 1960's, many individuals held relatively few stocks. Both the mean and median in their sample of investors were close to eleven different securities. The rise of index mutual funds in the last two decades has improved the diversification of individual investors, but directly held equity still accounts for two and one-half times as much of household wealth as *all* mutual funds, of which index funds are only a small part.

Perhaps the most striking example of incomplete diversification is the tendency of most households to own residential real estate near where they work. The returns on their human and physical capital may consequently be highly correlated. This generates a much less diversified portfolio than holding, for example, a real estate investment trust with a national real estate portfolio.

⁴Amos Tversky and Chip Heath (1991) present evidence that households behave as though unfamiliar gambles are riskier than familiar gambles, even when they assign identical probability distributions to the two gambles.

Window Dressing By Pension Fund Managers

By

JOSEF LAKONISHOK, ANDREI SHLEIFER, RICHARD THALER, AND ROBERT VISHNY*

The conventional wisdom on Wall Street is that portfolio managers are reluctant to produce annual reports that show holdings of shares that have sharply declined in value. One money manager is quoted by S. Jansson as saying: "Nobody wants to be caught showing last quarter's disasters.... You throw out the duds because you don't want to have to apologize for and defend a stock's presence to clients even though your investment judgment may be to hold" (1983, p. 139). The practice of deleting such shares from portfolios at year end is an example of "window dressing." Despite conventional wisdom, little is known of how widespread this practice is. In this paper, we look for evidence of window dressing among an important group of portfolio managers, those who manage pension funds.

As of December 1989, pension funds owned close to \$900 billion of American equities, about 25 percent of the stock market capitalization. Of this amount, about \$700 billion is actively managed and the rest is invested in index funds. Some plans manage their money internally, but more commonly they hire several money managers and split the pension plan's money among them. Plan sponsors typically evaluate fund managers once a quarter, but the main evaluation takes place at the end of the year. Based on these evaluations, assets are reallocated across money managers. Window dressing, if it occurs, is presumably a response to these evaluations.

Why might a fund manager engage in window dressing? The main focus of fund

evaluations is past performance relative to some benchmark, such as the S&P 500. Stock returns, however, are noisy and may not suffice to identify the manager's investment philosophy or to see whether he just got unlucky on a few stocks. As a result, sponsors may look at the actual portfolio holdings as well. To impress sponsors, fund managers may alter these portfolios at the end of the quarter, and especially at the end of the year, that is, window dress. A finding that money managers window dress is therefore evidence that managers are evaluated on a broader set of criteria than performance alone.

Selling losers is the most frequently mentioned form of window dressing. Pension funds can also reduce the pace of sale of winners, increase the purchases of winners and reduce the purchases of losers to impress the sponsors with the looks of their portfolios.¹ Some of these strategies, however, may not be as effective as selling losers. When a fund buys winners after they rose in price, sponsors would realize that these winners were not held during the price rise. If a fund purchases losers, its manager can probably explain that he bought them after they had fallen. On the other hand, slowing down the sale of winners might be as attractive as speeding up the sale of losers. We will examine these less frequently mentioned and perhaps less sophisticated forms of window dressing as well as the generic dumping losers strategy.

*University of Illinois, Champaign, IL 61820; Harvard University, Cambridge, MA 02138; Cornell University, Ithaca NY 14850; and University of Chicago, Chicago, IL 60637; respectively. We are grateful to Gil Beebower and Vasant Kamath for help with this project.

¹R. Haugen and Lakonishok (1988) suggest window dressing as a possible explanation of the "January Effect." Lakonishok and S. Smidt (1988) find a very substantial increase in the Dow Jones Industrial Average (an index of 30 large stocks) in the last week of December. They offer window dressing as a possible explanation of this finding.

I. The Data

Our analysis is based on a proprietary sample of 769 equity pension funds provided by SEI, a professional fund evaluation service. Equity funds hold at least 90 percent of their money in equities. The data set contains, for each fund, complete equity portfolio holdings at the end of each quarter from 1985 to 1989. Sponsors of most of these funds are corporations, but there are some state, municipal, and endowment pension funds as well. The total amount under management in these 769 funds at the end of 1989 is \$124 billion, or about 18 percent of the total actively managed holdings of pension funds. The average equity holdings of a fund at the end of 1989 are \$161 million; the largest 5 percent of the funds manage 65 percent of the money.

We do not observe all the trades that a fund makes in a given quarter because a fund might have bought and sold the same stock within that quarter. However, we can estimate purchases and sales based on portfolio changes from quarter end to quarter end. In the sample, in an average quarter, a fund buys 13 percent of the dollar value of its previous quarter's holdings, and sells 12 percent. Purchases exceed sales in part because funds receive dividends and in part because new contributions to the funds from the sponsors typically exceed payouts to the retirees. The turnover rate of 50 percent a year is typical for institutions. Pension funds' holdings are heavily concentrated in the largest capitalization stocks. While the bottom 50 percent of stocks in terms of size comprise 4.3 percent of market capitalization, they only represent 1.4 percent of pension funds' equity holdings.

To determine whether managers engage in window dressing, we must classify stocks into performance categories. At the end of each quarter, we take the CRSP universe of all NYSE, American, and NASDAQ stocks, and divide it into equal size quintiles based on stock returns over *the past year up to the end of that quarter*. This procedure is repeated every quarter, so the composition of each quintile changes each quarter. Since we know which stocks belong to which quin-

Purchases in Quintile as % of Total Purchases	.06	.19	.24	.28	.23

^aAll numbers are averaged over quarters and years.

tile, we can compute how much each fund holds, buys, and sells each quarter from each quintile. We use the average of beginning and end-of-quarter stock prices to estimate the total value of purchases and sales in each quintile by each fund.

Table 1 presents the fractions of their stock portfolios that funds as a whole hold in each past performance quintile (averaging over years and quarters) and the fraction of value of the CRSP universe in those quintiles. Table 1 also reports the fraction of purchases and sales that the funds as a whole make in each quintile. Holdings, sales, and purchases are all computed as if all money was in one aggregate fund. Table 1 shows that funds hold less of extreme losers and winners than exist in the universe. Funds hold only 5 percent of their portfolios in extreme losers, compared to 6 percent for the universe portfolio. They also hold 24 percent of their portfolios in extreme winners, compared to 28 percent for the universe. Obviously, funds are overrepresented in holdings of intermediate performance quintiles. One reason for the underrepresentation in extreme performance categories is that funds hold few small stocks, which are more likely to be among the extreme losers and extreme winners.

The evidence on purchases and sales reveals that trading is not always in proportion to holdings. Extreme losers represent 6 percent of both buying and selling, but just 5 percent of the holdings. Funds clearly *trade* extreme losers more. Perhaps they get rid of "mistakes," consistent with window dressing, but they also buy stocks they think are undervalued. Winners in contrast are overrepresented in sales relative to holdings and underrepresented in purchases relative to holdings. One way to summarize these data is that funds are generally contrarian (buy losers and sell winners) except they get rid of mistakes. The next section looks at the data more closely by comparing the fourth quarter to the first three.

II. Activity of Pension Funds by Quarter

All accounts of window dressing stress the relative importance of the year-end report. This section compares trading in the first three quarters with that in the fourth.

About 20 percent of the funds in an average quarter have zero holdings in the bottom performance quintile. To avoid statistical problems this raises when we examine the cross section of funds, we combine the bottom two quintiles, so the bottom group in a quarter is 40 percent worst performing stocks over the previous year. As a result of combining quintiles, funds holdings are more evenly distributed across the four groups.

Our measure of selling intensity in performance group i in quarter j by fund k is

$$(1) \quad \frac{\text{SELL}(i, j, k) / \text{HOLD}(i, j-1, k)}{\sum_i \text{SELL}(i, j, k) / \sum_i \text{HOLD}(i, j-1, k)}$$

where $\text{SELL}(i, j, k)$ is the value of sales by fund k in quarter j and group i , and $\text{HOLD}(i, j-1, k)$ is the value of holdings at the end of the previous quarter of the exact same stocks as those in performance group i in quarter j . Both SELL and HOLD are defined using the average of the beginning and end of quarter j prices. The numerator of (1) is the ratio of the sales in a performance group to holdings of the same stocks at the end of the previous quarter. The

denominator is the ratio of total sales in this quarter to holdings at the end of the previous quarter.

Equation (1) measures the selling intensity of a fund in a given performance group relative to the overall selling intensity. It corrects for the fact that funds might be selling less in a given group at a given time only because they are selling less of everything. If a fund sold 50 percent of the extreme winners it holds, but only 20 percent of its total holdings, its sales index for winners according to (1) is 2.5. Having computed this number for every fund, quarter and year, we average it over funds, years, and quarters 1-3, and then compare the average over quarters 1-3 to that for quarter 4.

Our measure of buying intensity by fund k in quarter j in performance group i is

$$(2) \quad \frac{\text{BUY}(i, j, k) / \sum_i \text{BUY}(i, j, k)}{\text{UNIV.HOLD}(i, j) / \sum_i \text{UNIV.HOLD}(i, j)}$$

where $\text{BUY}(i, j, k)$ is dollar purchases by fund k in group i in quarter j and $\text{UNIV.HOLD}(i, j)$ is the value of CRSP universe holdings in quarter j in group i . Again, both variables are computed using the average of beginning and end of quarter j prices. This number is the fraction of purchases that a fund makes in a performance category relative to the fraction of universe holdings in that performance category. So if 20 percent of a fund's purchases were in performance group 4, which is only 10 percent of the universe value in that quarter, the number for the fund in that quarter and quintile is 2.

Equation (2) controls for the value of each performance group that a fund can buy in every quarter, so purchases are scaled by the availability of stocks to buy. In this respect, the numbers for sales and purchases are parallel: the universe holdings define availability of stocks for purchase, and since funds in general do not take short positions, their own holdings define the availability of stocks for sale. We compute (2) for each fund, and then, as with measure

TABLE 2—SALES AND PURCHASES OF PENSION FUNDS BY QUARTER^a

Quintile	Quarter 1-3	Quarter 4	<i>t</i> -Test ^b
A. Sales Relative to Own Holdings			
1-2	1.32 (.026)	1.42 (.033)	1.75
3	.92 (.009)	1.02 (.084)	1.76
4	.91 (.007)	.89 (.014)	.24
5	1.44 (.053)	1.37 (.028)	1.22
B. Purchases Relative to Universe Holdings			
1-2	1.22 (.012)	1.33 (.024)	5.47
3	1.07 (.009)	1.09 (.017)	.097
4	1.01 (.008)	1.00 (.013)	.44
5	.90 (.009)	.88 (.015)	.71

^aSales number is from equation (1), purchase number is from equation (2). Both are averaged over funds and years.

^bFor difference, Quarter 1-3 = Quarter 4.

(1), average over funds and years for each quarter, and finally average over quarters 1 through 3 and compare that average to the one for quarter 4.

Table 2 presents the results, with cross-sectional standard errors for each quarter-performance group mean (in parentheses) and *t*-tests of equality of means for quarters 1-3 on the one hand and quarter 4 on the other. Unlike the results in Table 1 that were computed as if all holdings and trades were by one aggregate fund, in Table 2 we compute measures (1) and (2) first for each fund and then average over funds. This enables us to compute cross-sectional standard errors.

To begin, consider the findings for quarters 1-3. First, when it comes to purchases, funds are clearly contrarian: relative to availability they overbuy losers (ratio of 1.22) and underbuy winners (ratio of .90). Second, when it comes to sales funds oversell winners relative to their holdings (ratio of 1.44), but they also oversell losers (ratio of 1.32). Much less selling activity is observed in the middle quintile groups. These results confirm Table 1's findings that funds are

generally contrarian, except that they oversell extreme losers, consistent with the window-dressing hypothesis.

The comparison across quarters shows that the sale of losers relative to other quarters does accelerate in the fourth quarter, as it should if fund evaluations are most critical at the end of quarter four. In quarters 1-3, an average fund sells 32 percent more of the extreme losers (relative to its holdings of those losers) than it sells of all stocks; in quarter 4 this measure rises to 42 percent ($t = 1.75$). Consistent with window dressing, funds actively sell losers, especially in the fourth quarter.

What about other forms of window dressing? There is weak evidence of increased demand for winners in the fourth quarter: the sale of winners slows down ($t = 1.22$) although purchases do not rise. In addition, there is strong evidence of an increase in the purchases of losers in the fourth quarter relative to the first three ($t = 5.47$). In quarters 1-3, funds buy 22 percent more losers than they would if they bought stocks randomly from the universe, in quarter 4 this number rises to 33 percent. This result is robust in a variety of specifications. It is inconsistent with the simple version of window dressing, according to which just holding a portfolio that performed well (regardless of how long they have been held) is rewarded by the sponsors, but consistent with the more sophisticated view that buying losers after they have fallen can be justified to the sponsors. Funds might buy losers in the fourth quarter to provide liquidity for individuals who are selling them to realize losses in the current tax year. In this case, losers might be particularly good bargains in the fourth quarter.

To check robustness of these results, we have also performed the analysis by value-weighting the funds rather than equally weighting them. This amounts to assuming that all the funds' holdings and trades are done by one aggregate fund. The results, which are not presented, are qualitatively similar, although dumping losers is less pronounced when funds are value-weighted. For example, in quarters 1-3, value-weighted sales of losers relative to holdings

(corrected for all sales relative to holdings) are 1.0, but for quarter 4, this number is 1.06. This result suggests that window dressing is more prevalent in small funds. Indeed, we have performed the analysis for the 20 percent smallest funds as of the first quarter of 1985, and found a stronger propensity to sell losers in general, and in the fourth quarter in particular, for this subsample. For small funds, our measure of selling activity for losers is 1.37 in quarters 1–3 and 1.59 in quarter 4 ($t = 2.02$). More extensive window dressing by small funds suggests that it may be too hard to fool the sophisticated sponsors of large funds by window dressing, so their managers do not even try.

III. Conclusion

This paper took a preliminary look at portfolio strategies of a sample of 769 pension funds representing about 18 percent of private pension equity holdings in the United States. We have found that the average pension fund is contrarian, in that it buys more intensively stocks that have performed poorly and sells a disproportionately high fraction of stocks that have performed well. Such contrarian investment tendencies of the funds suggest that, contrary to a common perception, trading practices of institutions might reduce volatility of stock prices. This result obviously deserves a closer look.

We have also found evidence that in every quarter, funds sell poorly performing stocks disproportionately to their holdings,

that is, they get rid of “mistakes.” Moreover, the pace of dumping mistakes accelerates in the fourth quarter, consistent with the most common window-dressing strategy. This result is stronger for small funds. This finding supports the view that window dressing is a response to costly monitoring by fund sponsors of individual portfolio decisions, for it pays less for large funds, whose portfolios are monitored more frequently and completely, to pursue this practice.

Interestingly, purchases of losers also rise in the fourth quarter. This suggests that sponsors do not just look at the funds’ holdings of winners and losers, but recognize that buying losers after their prices fell might be smart. The overall evidence reveals some window dressing by pension fund managers. However, we stress that fourth-quarter strategies do not radically depart from the usual practice, but rather accentuate the typical investment strategy of funds: buy losers and sell both extreme winners and losers.

The Rationality Struggle: Illustrations from Financial Markets

By JAYENDU PATEL, RICHARD ZECKHAUSER, AND DARRYLL HENDRICKS*

For most economists it is an article of faith that financial markets reach rational aggregate outcomes, despite the irrational behavior of some participants, since sophisticated players stand ready to capitalize on the mistakes of the naive. (This process, which we call poaching, includes but is not limited to arbitrage.) Yet financial markets have been subject to speculative fads, from Dutch tulip mania to junk bonds, and to occasional dramatic losses in value, such as occurred in October 1987, that are hard to interpret as rational. Descriptive decision theory, especially psychology (see D. Kahneman et al., 1982), can help to explain such aberrant macrophenomena. Here we propose some behavioral explanations of overall market outcomes—specifically of financial flows, that are of considerable practical consequence to both policymakers and finance practitioners.

I. Behavioral Explanations of Market Macrophenomena

Investors play for significant stakes and have sustained opportunities for practice—both factors that should promote rational outcomes. C. Camerer (1987) shows that even in experimental markets, practice and significant payment do away with many anomalies. Moreover, since nonrational investors lose their funds, natural selection operates. Yet overall outcomes still may deviate from rationality, depending on two factors: the rationality of individual participants and the opportunities for poaching. Table 1 outlines the possibilities.

When participants are mostly rational and there are many opportunities for arbitrage (cell 1), we expect the efficient markets

TABLE 1—MODELING OUTCOMES OF SOCIAL INTERACTIONS: POACHABILITY AND RATIONALITY

Rationality ^a	Poachability/Arbitrage Potential:	
	High	Low
Full/Substantial; Individualistic	1) Efficient Markets	2) Anomalies Due to Incomplete Use and Flow of Information
Bounded/Low; Possibly Relativistic	3) Natural Selection Processes—pressures to restore efficiency	4) Grossly Inefficient Outcomes

^aNature/Proportion; Orientation.

paradigm to triumph. In cells 2 and 3, results are best explained by a merger of behavioral considerations and economic analysis. In 2, we expect economic paradigms to succeed, albeit with behavioral residues associated with problems of information flows. Purchases of open-end mutual funds, that cannot be poached, might display some anomalies. In 3, barring new entrants, processes of natural selection reduce the role of nonrational players over time. In cell 4, behavioral models should provide important insights into inefficient outcomes. No one can benefit from (poach on) the misbalanced portfolio or poor retirement funding decisions of another. Mistakes are to be expected, though beyond a threshold they may provoke a corrective response. (A 1990 information campaign by Harvard led to a one-third increase in employees' use of highly tax-advantaged supplemental retirement annuities, which had long been available.)

Cell 4 offers other interesting possibilities when preferences focus on relative, not absolute, outcomes. Judging one's allocations relative to those of others (as in labor market contests) requires less information gathering. This approach may also be dictated by envy. Such relative valuations could lead

decision makers to distort their own decisions, say in a "keep up with the Joneses" effort, or an attempt to move with the herd as a mechanism of protection.

We introduce two behavioral hypotheses to help explain financial phenomena: *Barn Door Closing* for mutual fund purchases, and *Herd Migration Behavior* for debt-equity ratios. Barn door closing, in the horse protection sense, refers to undertaking behavior today that would have been profitable yesterday. Herd migrations in finance occur when market conditions change, so that individual decision makers wish to alter their holdings substantially. Their transition is slowed because they seek protection by traveling with the herd.

II. Barn Door Closing—Purchases of Mutual Funds

The Nobel Prize-winning contributions of Markowitz and Sharpe address the rational portfolio choice problem and its implications for market pricing and efficient portfolio decisions. Their models imply that any individual's optimal mix of asset holdings will comprise a market portfolio (with assets in proportion to their total market value weights) and a riskless fund. When combined with the efficient markets hypothesis, this view leads to a passive (i.e., nontrading) portfolio strategy. The recently introduced multifactor Arbitrage Pricing Theory has similar implications, though the implied universal fund components remain to be satisfactorily identified. If all investors behaved as the financial models predict, observed flows should be due entirely to liquidity/consumption needs or incremental savings and should be explained by portfolio balance considerations.

In contrast, our earlier 1990 paper finds that relative flows across *individual* open-end equity mutual funds reflect 1) status quo bias, 2) a performance effect (i.e., investors' belief that a managed fund with a superior past will perform better than they could as individuals, a view encouraged by financial professionals), and 3) framing/data packaging. In cross-sectional time-series regressions (for 96 funds over 1975–87), we

explain 76 percent of the variance (R -squared) and highlight three interesting behavioral influences:

1) Persistence (Status quo bias). Other things equal, a one-dollar incremental flow induces a 75 cent flow in the following period. Although the avoidance of learning costs may justify some behavior persistence, we conjecture that investors (individuals more generally) shortchange important decisions by spreading their attention too evenly. Persistence may also spring from regret avoidance—an attempt to avoid a mistaken act of commission.

2) Past performance. A one-percentage-point return higher than the average fund's return implies a \$200,000 increased flow in the next year (where the median fund's size is \$80 million and the median flow is \$21 million).

3) Framing and data packaging. Rank measures, which are widely reported, appear to be more relevant in explaining flow patterns than are cardinal risk-adjusted performance measures.

In explaining net flows of funds from individuals to the mutual fund sector, barn door closing behavior may be relevant. Mutual fund purchasers may exhibit it because they: 1) rely on trends/patterns (widely prescribed for and practiced in commodities trading but contrary to efficient markets theory and near-martingale asset prices); or 2) engage in personal window dressing (realigning their portfolio to a desirable composition for the sample period experienced).

The traditional struggle of the multiple selves (see Thomas Schelling, 1982, pp. 57–82) is to control one's present self on behalf of the future self. We add a backward-looking feature. Individuals, seeking to contain regret, may try to remove reminders of their past errors. To invoke the agency framework, investors engaged in personal window dressing are imperfectly monitoring principals deceiving themselves into thinking better of their agents, namely their earlier selves.

If the barn door closing hypothesis is germane, individuals will buy more mutual funds after the stock market goes up, and sell after it plunges. Further, if there is

some behavioral threshold effect, this reaction will manifest itself mainly for large changes. Consider the fraction, f , of the U.S. household sector's flow of financial purchases (composed of direct and intermediated net purchases of equities, bonds, and short-maturity or demand deposits) directed to mutual funds. Quarterly data on f is constructed from the Federal Flow of Funds for the 1952Q1–1990Q1 period and excludes households' indirect claims, such as pensions. The fraction f appears mean stationary over the sample period, though during the 1980's f is higher (0.11) than the overall mean (0.05).

In a regression of f on four of its own lags, changes in Treasury bill interest rates, and returns on the equity market (proxied by the value-weighted NYSE index), we observe an economically large and statistically significant positive coefficient on equity returns that is consistent with barn door closing. (Simultaneity problems are avoided since most mutual funds are open end, and hence their supply of shares is highly elastic.) When the market has done well, one wishes that one had invested there, rather than purchase short-term assets (that normally represent more than 50 percent of the households' flows) and fixed-interest assets (that represent about 21 percent), and vice versa. A regression that decomposes equity returns into large ($> |10 \text{ percent}|$) and small changes suggests that barn door closing is most relevant when a threshold has been exceeded. The coefficient on large changes is 0.35 (t -statistic of 4.09), whereas the one on small changes is insignificant (0.06 with a t -statistic of 0.47). Thus a 1 percent change in equity returns beyond a threshold change of 10 percent induces a 6 percent change in the rate of investment in mutual funds by households. (The results are not driven by some subperiod; of the 25 large-change observations, 10 are from the 1950's and 1960's, and 15 are from the 1970's and 1980's.)

III. Financial Herd Migrations—Corporate Debt-Equity Ratios

Migrating birds and trekking wildebeest all know that traveling in a group offers protection. Financial players also may mi-

grate in herds, as when firms increase their debt-equity, S&Ls invest in junk bonds, and banks increase their Third-World debt holdings. These transitions are not instantaneous for many reasons, including the superior information aggregation and mutually informed choices that result from movements in clusters. As with our animal friends, it may be dangerous to get too far out of line.

Each decision maker in a financial migration balances the benefits of more quickly approaching the optimum against the costs of moving away from the herd. As each takes small steps, the whole process ratchets along. Financial migrations, unlike periodic animal migrations, tend to chart unfamiliar territories, and the optimal destination often is not clear. This uncertainty, combined with the natural tendency of individuals to free ride on the information of others, provides the potential for overshooting; as we saw with Third-World debt, or proceeding a while along the wrong path (like the wildebeest who plunge one after another into a ravine, none having had sufficient incentive to worry about his own direction). Birds, scientists now believe, are guided to their distant destinations by the stars and magnetic fields, through navigational methods buried deep in their genes. Human decision makers are less blessed, and must call on their brains.

Even the most clear-sighted financial navigator may be deterred from steering his own course if there is herding on the other side of the market. Banks have delayed writing down doomed real estate loans because the market "would not understand." Corporations considering an increase in their debt-equity ratio had to be concerned about the perceptions of lenders and investors, who might be unfamiliar with the Modigliani-Miller theorem. Bankers hesitate to lend to a firm whose debt-equity ratio tops its industry.

We examined the annual ratios of debt (book value) to equity (market value) for the 200 largest firms (by sales) during the period 1971–89. On the COMPUSTAT database, 15 of these firms had some missing observations, and 3 clearly had outlier debt-equity ratios (in excess of 5): this left us with a

usable sample of 182 firms. We assigned firms to 10 industries based on a reasonable classification of two-digit SIC codes. Over the sample period, there was a persistent overall rise in debt-equity ratios, though considerable heterogeneity across industries and firms (R. Taggart, 1985).

This pattern might be explained by a cost-of-adjustment model. If benefits from movement are linear and costs of adjustment increasing, and if the parameters are constant for the period under study, then each firm would adjust a fixed amount per period; that is, exhibit a local trend regardless of the behavior of other firms.

Our simple herd migration model offers an alternative explanation with additional linkages. Suppose, for the period studied, there is a linear per unit benefit from moving the debt-equity ratio toward its optimum (that is possibly firm-specific and time-varying), but a quadratic penalty for deviations from the crowd (i.e., other firms in one's industry). Under this scenario, parallel to the solution for linear-quadratic models for inventory, the firm's ideal ratio will be a linear weighting of its own past ratio plus the industry's expected ratio. We investigate the herd migration explanation by regressing the firm's debt-equity ratio on two own lags and one lag of the industry ratio. (The expected industry ratio is proxied by its lagged value; its contemporaneous value may exhibit a positive relation simply because of common shocks that influence the market value of equity across firms in an industry.)

A herd migration tendency is indicated by a significant positive sign (a *t*-statistic above +2) on the industry ratio. For 3 of the 10 industries, less than 15 percent of the firms exhibit such tendencies significantly. The proportions were significantly higher for the other 7 industries: food & tobacco, 11/17; paper, lumber & printing, 8/24; oil & gas, 7/13; chemicals, 7/24; electrical products & machinery, 7/12; transportation & communication, 7/17; wholesale & retail trade, 6/26. The median coefficient on the industry ratio for all 182 firms was 0.2; 35 percent of all the coefficients had *t*-statistics greater than +2, 23 percent were between +1 and +2, and 22 percent were negative.

IV. Concluding Remarks

Looking at flows in financial markets, a relatively unexplored area, we have illustrated the role of such behavioral phenomena as status quo bias, barn door closing, and herd migrations in influencing market outcomes. (These ideas will be elaborated in a forthcoming article in *Theory and Decision*.) The mere survival of many financial markets needs explanation. What sustains their flows of new funds? Absent substantial hedging activity, a large proportion of the individual participants (speculators) in a financial market must have negative expectations. Markets must have certain characteristics to continually lure in losing investors (Zeckhauser and V. Niederhoffer, 1983).

Monday morning quarterbacking may provide part of the explanation. Fans of professional football often believe (with the unacknowledged benefit of hindsight) that they would have been better able than their team's coaches/quarterbacks to identify the strategy that would have won the weekend game. In financial markets, similarly, participants examine past movements and convince themselves they would have made the right choices had they been involved, implying they could do so in the future. To confirm the prevalence of Monday morning quarterbacking, the reader should ask finance-oriented friends whether they sensed that the stock market was "clearly" overpriced just before the October 1987 crash.

We conclude poetically:

In the players, not the market, may rational ways inhere.

(But also vice versa—received doctrine makes it clear.)

From the traders to the tickers, you should not expect to see

Either easy aggregation, or pat synecdoche.

Rational Addiction and the Effect of Price on Consumption

By GARY S. BECKER, MICHAEL GROSSMAN, AND KEVIN M. MURPHY*

Legalization of such substances as marijuana, heroin, and cocaine surely will reduce the prices of these harmful addictive drugs. By the law of the downward-sloping demand function, their consumption will rise. But by how much? According to conventional wisdom, the consumption of these illegal addictive substances is not responsive to price.

However, conventional wisdom is contradicted by Becker and Murphy's (1988) theoretical model of rational addiction. The Becker-Murphy (B-M) analysis implies that addictive substances are likely to be quite responsive to price. In this paper, we summarize B-M's model of rational addiction and the empirical evidence in support of it. We use the theory and evidence to draw highly tentative inferences concerning the effects of legalization of currently banned substances on consumption in the aggregate and for selected groups in the population.

Addictive behavior is usually assumed to involve both "reinforcement" and "tolerance." Reinforcement means that greater past consumption of addictive goods, such as drugs or cigarettes, increases the desire for present consumption. But tolerance cautions that the utility from a given amount of consumption is lower when past consumption is greater.

These aspects of addictive behavior imply several restrictions on the instantaneous utility function

$$(1) \quad U(t) = u[c(t), S(t), y(t)],$$

where $U(t)$ is utility at t , $c(t)$ is consumption of the addictive good, $y(t)$ is a non-addictive good, and $S(t)$ is the stock of "addictive capital" that depends on past consumption of c and on life cycle events. Tolerance is defined by $\partial u / \partial S = u_s < 0$, which means that addictions are harmful in the sense that greater past consumption of addictive goods lowers current utility. Stated differently, higher $c(t)$ lowers future utility by raising future values of S .

Reinforcement ($dc/dS > 0$) requires that an increase in past use raises the marginal utility of current consumption: ($\partial^2 u / \partial c \partial S = u_{cs} > 0$). This is a sufficient condition for myopic utility maximizers who do not consider the future consequences of their current behavior. But rational utility maximizers also consider the future harmful consequences of their current behavior. Reinforcement for them requires that the positive effect of an increase in $S(t)$ on the marginal utility of $c(t)$ exceeds the negative effect of higher $S(t)$ on the future harm from greater $c(t)$.

Becker-Murphy (p. 680) show that a necessary and sufficient condition for reinforcement near a steady state (where $c = \delta S$) is

$$(2) \quad (\sigma + 2\delta)u_{cs} > -u_{ss},$$

where u_{cs} and u_{ss} are local approximations near the steady state, σ is the rate of time preference, and δ is the rate of depreciation on addictive capital. Reinforcement is stronger, the bigger the left-hand side is relative to the right-hand side. Clearly,

$u_{cs} > 0$ is necessary if u is concave in S ($u_{ss} < 0$); that is, if tolerance increases as S increases.

It is not surprising that addiction is more likely for people who discount the future heavily (a higher σ) since they pay less attention to the adverse consequences. Addiction to a good is also stronger when the effects of past consumption depreciate more rapidly (δ is larger), for then current consumption has smaller negative effects on future utility. The harmful effects of smoking, drinking, and much drug use do generally disappear within a few years after a person stops the addiction unless vital organs, such as the liver, get irreversibly damaged.

Reinforcement as summarized in equation (2) has the important implication that the consumption of an addictive good at different times are complements. Therefore, an increase in either past or expected future prices decreases current consumption. The relation between these effects of past and future prices depends on both time preference and the depreciation rate.

Figure 1 illustrates several implications of our approach to addiction, where $S(t)$ is measured along the horizontal axis and $c(t)$ along the vertical one. The line $c = \delta S$ gives all possible steady states where c and S are constant over time. The positively sloped curves A^1 give the relation between c and S for an addicted consumer who has a particular utility function, faces given prices of c and y , and has a given wealth. The initial stock (S^0) depends on past consumption and past life cycle experience. Both c and S grow over time when S^0 is in the interval where A^1 is above the steady-state line, and both fall over time when S^0 is in the intervals where A^1 is below the steady-state line.

Figure 1 shows clearly why the degree of addiction is very sensitive to the initial level of addictive capital. If S^0 is below S^1 in the figure, a rational consumer eventually lays off the addictive good. But if S^0 is above S^1 , even a rational consumer becomes addicted, and ends up consuming large quantities of the addictive good.

The curve A^1 intersects the steady-state line at two points: $c^1 = \delta S^1$, and $c^{*1} = \delta S^{*1}$. Other relevant points are where $c = 0$ and

FIGURE 1

$S \leq S^1$. The second point and third set of points are locally stable. If initially $c = 0$, $S \leq S^1$, and a divorce or other events raise the stock of addictive capital to a level below S^1 , c may become positive, but eventually the consumer again refrains from consuming c . Similarly, if initially $c = c^{*1} = \delta S^{*1}$, c falls at first if say finding a good job lowers S from S^{*1} to a level $> S^1$. But c then begins to rise over time and returns toward c^{*1} . The other steady state, $c^1 = \delta S^1$, is locally and globally unstable: even small changes in S cause cumulative movements toward $c = 0$ or $c = c^{*1}$.

Unstable steady states are an important part of the analysis of rational addictions, for they explain why the same person is sometimes heavily addicted to cigarettes, drugs, or other goods, and yet at other times lays off completely. Suppose the consumer starts out at $c^{*1} = \delta S^{*1}$, and experiences favorable events that lower his stock of addictive capital below S^1 , the unstable steady state with A^1 . The consumer goes from being strongly addicted to eventually giving up c entirely. If A^1 is very steep when S is below the unstable steady state (if reinforcement is powerful in this interval), consumers would quit their addiction "cold turkey" (see the more extended analysis in B-M).

To analyze rational addicts' responses to changes in the cost of addictive goods, suppose they are at $c^{*2} = \delta S^{*2}$ along A^2 , and that a fall in the price of c raises the demand curve for c from A^2 to A^1 . Consumption increases at first from c^{*2} to \hat{c} , and then c grows further over time since \hat{c} is above the steady-state line. Consumption grows toward the new stable steady state at

$c^*1 = \delta S^*1$. This shows that long-run responses to price changes exceed short-run responses because initial increases in consumption of addictive goods cause a subsequent growth in the stocks of addictive capital, which then stimulates further growth in consumption.

Since the degree of addiction is stronger when A is steeper, and since long-run responses to price changes are also greater when A is steeper, strong addictions do not imply weak price elasticities. Indeed, if anything, rational addicts respond more to price changes in the long run than do nonaddicts.¹ The short-run change is smaller than the long-run change because the stock of addictive capital is fixed. Even in the short run, however, rational addicts respond to the anticipated growth in future consumption since future and current consumption of addictive goods are complements for them. But the *ratio* of short- to long-run responses does decline as the degree of addiction increases.²

The presence of unstable steady states for highly addictive goods means that the full effect of a price change on consumption could be much greater for these goods than the change between stable steady states given in footnote 1. Households with initial consumption capital between \underline{S}^2 and \underline{S}^1 in Figure 1 would be to the left of the unstable steady state at \underline{S}^2 when price equals p^2 , but they would be to the right of the unstable steady state at \underline{S}^1 when price equals p^1 . A reduction in price from p^2 to p^1 greatly raises the long-run demand by these households because they move from low initial

consumption to a stable steady state with a high level of consumption.

The total cost of addictive goods to consumers equals the sum of the good's price and the money value of any future adverse effects, such as the negative effects on earnings and health of smoking, heavy drinking, or dependence on crack. Either a higher price of the good (due perhaps to a larger tax) or a higher future cost (due perhaps to greater information about health hazards) reduces consumption in both the short and long run.

It is intuitively plausible that as price becomes a bigger share of total cost, long-run changes in demand induced by a given percentage change in the money price get larger *relative* to the long-run changes induced by an equal percentage change in future costs (see our 1991 paper, fn. 3). Money price tends to be relatively more important to poorer and younger consumers, partly because they generally place a smaller monetary value on health and other harmful future effects.

Poorer and younger persons also appear to discount the future more heavily (this is suggested by the theoretical analysis in Becker, 1990). It can be shown that addicts with higher discount rates respond more to changes in money prices of addictive goods, whereas addicts with lower rates of discount respond more to changes in the harmful future consequences.³

These implications of rational addiction can be tested with evidence on the demand for cigarettes, heavy consumption of alcohol, and gambling. Our earlier paper (1990)

¹Becker-Murphy show (equation (18), p. 685) that the long-run response between stable steady states to a permanent change in p_c is $dc^*/dp_c = \mu/\alpha_{cc}B'$, where μ is the marginal utility of wealth. The term B' measures the degree of addiction, where B' ranges between 1 (no addiction) and 0 for an addictive good that has a stable steady state.

²One can show that a rational addict's short-run response to a permanent change in p_c equals $dc_s/dp_c = -(\lambda/\delta)(dc^*/dp_c)$, where $-\delta \leq \lambda \leq 0$, and λ is larger when the degree of addiction is stronger (see B-M, pp. 679–80). Therefore, the ratio of the short- to long-term response gets smaller as the degree of addiction (measured by λ) is larger. But one can also show that dc_s/dp_c itself gets larger as the degree of addiction increases.

³If u is concave, $-\delta^2 u_{cc} - u_{ss} > 2\delta u_{cs}$. This implies that either or both of the following inequalities hold: $-u_{ss}/\delta^2 > u_{cs}/\delta$, and $-u_{cc} > u_{cs}/\delta$. We assume both hold. The second inequality states that an increase in c between steady states reduces the marginal utility of c by more than the increase in S raises it. The first inequality assumes that the increase in S has a larger effect on its marginal utility than does the increase in c .

The absolute value of the long-run change in c induced by a change in p_c is raised by an increase in σ if $-u_{ss} > \delta u_{cs}$. Similarly, the absolute value of the long-run change in c with respect a change in future costs is reduced by an increase in σ if $-u_{cc}\delta > u_{cs}$. (For more details, see our 1991 paper, fn. 4).

fit models of rational addiction to cigarettes to a time-series of state cross sections for the period 1955–85. We find a sizable long-run price elasticity of demand ranging between $-.7$ and $-.8$, while the elasticity of consumption with respect to price in the first year after a permanent price change (the short-run price elasticity) is about $-.4$. Smoking in different years appear to be complements: cigarette consumption in any year is lower when both future prices and past prices are higher.

Frank Chaloupka (forthcoming) analyzes cigarette smoking over time by a panel of individuals. He finds similar short- and long-run price elasticities to those we estimate, and that future as well as past increases in cigarette prices reduce current smoking. He also finds that smoking by the less educated responds much more to changes in cigarette prices than does smoking by the more educated; a similar result has been obtained by Joy Townsend (1987) with British data. Eugene Lewit et al. (1981) and Lewit and Douglas Coate (1982) report that youths respond more than adults to changes in cigarette prices. By contrast, the information that began to emerge in the early 1960's about the harmful long-run effects of smoking has had a much greater effect on smoking by the rich and more educated than by the poor and less educated (see Phillip Farrell and Victor Fuchs, 1982, for the United States; Townsend for Britain).

Philip Cook and George Tauchen (1982) examine variations in death rates from cirrhosis of the liver (a standard measure of heavy alcohol use), as well as variations in per capita consumption of distilled spirits in a time-series of state cross sections for 1962–77. They find that state excise taxes on distilled spirits have a negative and statistically significant effect on the cirrhosis death rate. Moreover, a small increase in prices in a state's excise tax lowers death rates by a larger percentage than it lowers per capita consumption.

Pamela Mobilia (1990) applies the rational addiction framework to the demand for gambling at horse racing tracks. Her data consist of a U.S. time-series of racing track cross sections for the period 1950–86 (tracks

over time are the units of observation). She measures consumption by the real amount bet per person attending (handle per attendant), and price by the takeout rate (the fraction of the total amount bet that is retained by the track). Her findings are similar to those in the rational addictive studies of cigarettes. The long-run price elasticity of demand for gambling equals $-.7$ and is more than twice as large as the short-run elasticity of $-.3$. Moreover, an increase in the current takeout rate lowers handle per attendant in both past and future years.

The evidence from smoking, heavy drinking, and gambling rather strongly supports our model of rational addiction. In particular, long-run price elasticities are sizable and much bigger than short-run elasticities, higher future as well as past prices reduce current consumption, lower-income persons respond more to changes in prices of addictive goods than do higher-income persons, whereas the latter respond more to changes in future harmful effects, and younger persons respond more to price changes than older persons. It seems reasonable to us that what holds for smoking, heavy drinking, and gambling tends to hold also for drug use, although direct evidence is not yet available, and many experts on drugs would be skeptical. Lacking the evidence, we simply indicate what to expect from various kinds of price changes if responses of drug addicts are similar to those of persons addicted to other goods.

To fix ideas, consider a large permanent reduction in the price of drugs (perhaps due to partial or complete legalization) combined with much greater efforts to educate the population about the harm from drug use. Our analysis predicts that much lower prices could significantly expand use even in the short run, and it would surely stimulate much greater addiction in the long run. Note, however, that the elasticity of response to large price changes would be less than that to modest changes if the elasticity is smaller at lower prices.

The effects of a fall in drug prices on demand would be countered by the education program. But since drug use by the poor would be more sensitive to the price fall than to greater information about harm-

ful longer-run effects, drug addiction among the poor is likely to become more important relative to addiction among the middle classes and rich. For similar reasons, addiction among the young may rise more than that among other segments of the population.

A misleading impression about the reaction to permanent price changes may have been created by the effects of temporary police crackdowns on drugs, or temporary federal "wars" on drugs. Since temporary policies raise current but not future prices (they would even lower future prices if drug inventories are built up during a crackdown period), there is no complementary fall in current use from a fall in future use. Consequently, even if drug addicts are rational, a temporary war that greatly raised street prices of drugs may well have only a small effect on drug use, whereas a permanent war could have much bigger effects, even in the short run.

Clearly, we have not provided enough evidence to evaluate whether or not the use of heroin, cocaine, and other drugs should be legalized. A cost-benefit analysis of many effects is needed to decide between a regime in which drugs are legal and one in which they are not. What this paper shows is that the permanent reduction in price caused by legalization is likely to have a substantial positive effect on use, particularly among the poor and young.

Alcohol Consumption During Prohibition

By JEFFREY A. MIRON AND JEFFREY ZWIEBEL*

The burgeoning debate over drug legalization in the United States has drawn renewed attention to the nation's experience with Prohibition. Although the parallels between the criminalization of alcohol and the criminalization of drugs are not exact, Prohibition provides a natural setting in which to examine the impact of legal restrictions on the use of substances such as alcohol or drugs. The popular media asserts widely divergent accounts of the changes in alcohol consumption during Prohibition, claiming both that drinking increased substantially and that drinking fell to a small fraction of its pre-Prohibition level. To date, however, most such assertions have been based on little hard evidence.

It should come as no surprise that accurate data on alcohol consumption during Prohibition do not exist. Perhaps more surprisingly, there have been few serious attempts to estimate consumption using related statistics. With the notable exception of Clark Warburton (1932), which has the drawback of being conducted in the middle of Prohibition, we know of no careful attempt to estimate this consumption. We employ Warburton both as a starting point and as a comparison for our estimation.

Attempts to estimate alcohol consumption from related variables suffer the drawback that Prohibition may have altered the relationship between these series and alcohol consumption. We address this problem by using data drawn from widely varying sources; plausibly the biases in these series will be unrelated. In particular, we use mortality, mental health, and crime statistics to

estimate the consumption of alcohol during Prohibition.

We find that alcohol consumption fell sharply at the beginning of Prohibition, to approximately 30 percent of its pre-Prohibition level. During the next several years, however, alcohol consumption increased sharply, to about 60–70 percent of its pre-Prohibition level. The level of consumption remained virtually the same immediately after Prohibition as during the latter part of Prohibition, although consumption increased to approximately its pre-Prohibition level during the subsequent decade.

I. Historical Background

The Prohibition movement in the United States traces its origins to the mid-nineteenth century. It was not until the 1910's, however, that sufficient support was garnered to make national prohibition a reality. During the latter half of this decade, many states enacted dry laws, and in 1917 Congress provided for Wartime Prohibition. National Prohibition became effective in January 1920 under the 18th Amendment to the Constitution. Prohibition remained in effect for almost 14 years, until rescinded by the 21st Amendment in December 1933.

By the mid-1920's it was apparent that at best limited success had been achieved in prohibiting alcohol consumption. Initially Congress responded with increased enforcement. Money appropriated for enforcing Prohibition increased from \$6.3 million in 1921 (the first year of large-scale enforcement) to \$9.2 million in 1925 and to \$13.4 million in 1930 (U.S. Department of Treasury, 1930, p. 2). However, the inability to restrict the illegal trade and the inevitable accompanying corruption eventually led to widespread public disenchantment with Prohibition.

By the turn of the decade, popular sentiment had undergone a radical turnabout on

Prohibition.¹ The 1930 election saw the anti-Prohibitionists' strength increase, and by 1932 the Democratic Party supported outright repeal. By 1933, support for repeal was widespread in Congress. In February, both Houses approved the 21st Amendment, and by December, three-quarters of the states had ratified the amendment, ending the experiment of Prohibition.

II. Data and Methodology

Estimating alcohol consumption during Prohibition is complicated by the possibility that Prohibition was accompanied by changes in attitudes or actions that affected underlying relationships. Thus, for example, while the number of arrests for drunkenness may be closely related to alcohol consumption, Prohibition could lead to more vigorous enforcement of drunkenness laws, raising the number of drunkenness arrests for a fixed level of consumption. Alternatively, it could drive more drinking into the home, thereby lowering the drunkenness arrest tally. Similarly, deaths due to alcoholism may increase due to low-quality alcohol. We address such complications by comparing estimates from several diverse sources.

The series that we use to estimate alcohol consumption are the death rate from cirrhosis of the liver, the death rate from alcoholism, the number of patients per capita admitted to hospitals for the first time with alcoholic psychosis, and the rate of drunkenness arrests. (The Data Appendix, available upon request, provides the details of the construction of these series.) For each of the series, we posit the relation.

$$(1) \quad \ln Y_t = \alpha + \beta t + \gamma \ln X_t + \varepsilon_t,$$

¹For example, in 1915 popular magazine articles in favor of Prohibition outnumbered those opposed 20 to 1; by 1930 this ratio had reversed to 1 to 2 (see Andrew Sinclair, 1962, p. 332.). Polls taken by *Literary Digest* indicate that while in 1922 only 1 in 5 individuals favored complete repeal, by 1930 all states but 5 showed a majority in favor of repeal or modification, and by 1932 all states but 2 had a majority in favor of repeal (Sinclair, p. 335).

where X_t is alcohol consumption, t is a time trend, and Y_t is one of the four series related to alcohol consumption. We estimate this equation for the years during the 1900–50 period for which data for the particular series are available, exclusive of the Prohibition years 1920–35.² We then use the estimated parameters from (1) to construct consumption from 1920 to 1935.

While Warburton assumes linear relationships between alcohol consumption and various statistics, we assume a log linear relationship because this is the simplest specification satisfying the restriction that no alcohol consumption should imply no deaths from alcoholism, no alcoholic psychosis and no drunkenness arrests (although the same cannot be said about cirrhosis). Additionally, this model fits well for all four series, and a linear specification yields similar results. The trend is included to capture other developments over time, such as a tendency to treat more psychotic patients or an improvement in the treatment of cirrhosis.

Including lagged consumption in these regressions does not substantively change the results. For cirrhosis and drunkenness, the coefficients on lagged consumption are statistically insignificant. For deaths due to alcoholism and admittances for alcoholic psychosis, lagged values of alcohol consumption do enter significantly, but the estimates of alcohol consumption based on regressions with these lags are not substantially different from those based on the regressions without lags.

The fact that lagged consumption does not explain cirrhosis may appear surprising, since cirrhosis results from a lengthy history of alcohol consumption. While this may be

²The estimates reported below are robust to extending the sample period. We use data only through 1950 to minimize the effects of changes in underlying relationships and to avoid definitional changes in the reported data. We exclude 1934–35 from the sample because it took several years after the end of Prohibition for the legal producers to fully recapture industry control. For alcoholic psychosis, we fit the model only through 1940 because this series (like other mental health series) is quite volatile during World War II.

so, the data seem to suggest that one must be presently drinking to die from cirrhosis. This view is mirrored in statistics that show a steep drop in cirrhosis when consumption falls both during wartime Prohibition and at the onset of constitutional Prohibition. If, however, the true specification for cirrhosis involves lags that we do not include, our estimates of consumption are likely overstated immediately after the onset of Prohibition (when consumption falls) and understated in following years.³

III. Results

Table 1 presents ordinary least squares estimates of equation (1). Each row represents a regression with one of the four dependent variables. Low Durbin-Watson statistics indicate the likelihood of serial correlation, so we report robust standard errors calculated using Whitney Newey and Kenneth West's (1987) procedure. For each of the four series, the model explains a large portion of the variation in the dependent variable. The \bar{R}^2 exceeds .90 for alcoholism, cirrhosis, and drunkenness and is .79 for alcoholic psychosis. Alcohol consumption is significant at the .01 level of significance for all series except alcoholism deaths, for which it is significant at the .03 level. The time trend is significant at the .01 level for cirrhosis, alcoholism, and psychosis, but is insignificant at the .05 level for drunkenness arrests.

The four estimates of consumption from 1920 to 1935, and true consumption before and after this period, are graphed in Figure 1. Comparing the four series we find similar estimates from cirrhosis, drunkenness, and psychosis, but substantially higher estimates from alcoholism. We suspect that the alcoholism series overstates true consumption during Prohibition due to decreased alcohol quality. In particular, the consumption of wood or denatured alcohol likely produced

TABLE 1—ESTIMATES OF EQUATION (1)

Dependent Variable	Sample Period	Independent Variables			\bar{R}^2
		Constant	Trend	Alcohol	
Cirrhosis	1900–50	2.560 (.046)	–.007 (.001)	.619 (.046)	.924
Alcoholism Deaths	1900–50	2.366 (.221)	–.027 (.002)	.802 (.344)	.902
Drunkenness Arrests	1910–29	4.186 (.345)	.013 (.007)	.902 (.076)	.933
Alcoholic Psychosis	1910–40	.691 (.123)	.008 (.002)	.949 (.078)	.794

Notes: 1) Newey-West standard errors are shown in parentheses. 2) Alcohol consumption is measured in gallons of pure alcohol per capita. 3) Cirrhosis, alcoholism deaths, alcoholic psychosis, and drunkenness arrests are all measured in per capita terms. 4) The equations are estimated over the sample periods indicated, excluding the years 1920–35.

more alcoholism deaths for given consumption. Similarly, cirrhosis, which provides the lowest estimates, may understate consumption if the functional relationship is misspecified, as discussed above.

All four estimates, however, show a similar steep initial decline in consumption followed by a steady increase. Consumption falls immediately after enactment of Prohibition to 20 to 40 percent of its pre-Prohibition level. Alcoholism, drunkenness, and psychosis estimates indicate a sharp rebound in consumption from 1921 to 1927 and a less dramatic increase after 1927. The cirrhosis estimates exhibit a similar pattern, but with a smaller initial decline in consumption and a more moderate subsequent increase. In the later years of Prohibition, cirrhosis, drunkenness, and psychosis estimate consumption to be 50 to 70 percent of its pre-Prohibition value, while alcoholism estimates small increases in consumption.

The estimates in Figure 1 improve on Warburton's by employing data beyond 1929 (both in fitting the model and in estimating consumption at the end of Prohibition) and by considering a more reasonable functional relationship. Nonetheless, both studies yield

³For further discussion of this issue and a more detailed model of the relation between alcohol consumption and the cirrhosis death rate, see P. J. Cook and G. Tauchen (1982).

FIGURE 1. ESTIMATED ALCOHOL CONSUMPTION

similar results. Warburton considers agricultural sources of production, death rates, and arrests for drunkenness in estimating consumption. He estimates that consumption per capita is around 65 percent of pre-Prohibition levels by 1925 and around 71 percent by 1929. When comparing results from the same series, our estimates are slightly higher than Warburton's. Overall, however, his average estimates are about the same as ours because his highest estimates are from agricultural production, which we do not consider.

While for three of our series we find reductions in consumption compared to pre-Prohibition levels, the decline is much more modest when compared to post-Prohibition levels. The level of consumption in 1937–40 is about the same as our average estimate for the last years of Prohibition. (However, consumption rises to pre-Prohibition levels over the next decade.) Whether the pre- or post-Prohibition benchmark is appropriate depends both on what question is being asked and to what one attributes the difference in pre- vs. post-Prohibition consumption. This difference may result from demographic factors (for example, a smaller percentage of immigrants who drank more, or a different age composition of the population), or a continuation of the social trend toward less drinking that began well before Prohibition. Either explanation would imply that Prohi-

bition had little to do with the observed change in drinking patterns. Conversely, the difference may result from a change in social attitudes due to Prohibition. Trying to distinguish between these competing hypotheses is beyond the scope of this paper. However, as far as the debate on drug legalization is concerned, the comparisons to post-Prohibition consumption are more pertinent than those to pre-Prohibition consumption.

IV. Discussion

There are several channels through which Prohibition may affect alcohol consumption. First, Prohibition increases supply costs, as these must include the cost of evading detection and the potential cost of punishment. This implies a higher equilibrium market price and less consumption. Second, Prohibition inhibits consumer access to alcohol by raising search costs, making quality dubious, and increasing the possibility of being cheated. Third, Prohibition may create a prevailing sentiment that a certain good is "bad" or "immoral," thereby decreasing consumer demand. Finally, Prohibition may deter some individuals' consumption because of "respect for the law." Even though consumption per se was not illegal, purchasing alcohol during Prohibition involved doing business with criminals.

Our results suggest that of these reasons, only the first two contributed significantly to the changes in alcohol consumption during Prohibition. A careful consideration of price quotes in newspapers by Warburton suggests that prices in 1930 were approximately three times as high as pre-Prohibition prices.⁴ Hence even if price changes alone were responsible for changes in demand,

⁴See Warburton (pp. 113, 116, and 166). We assume that the cost of homemade alcohol was at least as high as the market price after accounting for time and potential punishment costs. If it had been much cheaper, there would not have been an illegal alcohol industry. Note that another interpretation of higher prices and lower consumption during Prohibition is that illegal suppliers possessed and exercised monopoly power.

global price elasticities would have to be extremely low, around .1.⁵ This suggests that the effect of all other avenues that could theoretically lower demand had a negligible impact.

This is consistent with anecdotal evidence that suggests that the effect of public sentiment in reducing consumption is unclear. Some evidence even suggests Prohibition made consumption more desirable by endowing drinking with an illicit romance and sense of adventure. Thus, one plausible interpretation of the small changes in consumption given the change in price is that the demand curve for alcohol shifted out during Prohibition.

There are important similarities and differences to keep in mind when trying to draw inferences from Prohibition on how drug legalization might change consumption. Prices of illegal drugs appear to have been forced further above their production costs than that of alcohol during Prohibition, presumably because of more stringent enforcement. This effect, however, may be countered by a more inelastic demand for illegal drugs than for alcohol. There seems to be no compelling reason why respect for the law or other social impediments are any more likely to have a significant impact on drug consumption than they did on alcohol consumption during Prohibition. Thus, we hypothesize that any increase in consumption due to changes in social attitudes following drug legalization is likely to be small.

V. Conclusion

We find that while alcohol consumption declined sharply at the onset of Prohibition,

within several years it rebounded to 60–70 percent of its initial value and did not increase substantially immediately following the repeal of Prohibition. Claims either that consumption during Prohibition increased significantly or that it fell to a small fraction of previous usage can be patently rejected. Changes in consumption during Prohibition were modest given the change in price. This suggests that legal deterrents had little effect on limiting consumption outside of their effect on price. Social pressure and respect for the law did not go far in reducing consumption during Prohibition. We speculate that this is likely to be true as well with illegal drugs today, and therefore claims based on such arguments exaggerate the extent to which drug consumption would increase upon legalization.

Of course, any debate on drug legalization is incomplete if it solely considers changes in consumption. The negative effects accompanying any increases in consumption are costs that have to be weighed against various benefits of drug legalization. These benefits are likely to include an elimination of the violent drug culture that results from the battle for illegal profits, a reduction in overdoses from impure drugs, a reduction in robberies and burglaries committed by addicts who pay inflated drug prices, the stabilization of Latin American regimes fighting control battles with drug lords, the ability to combat the spread of AIDS from needle exchanges more effectively, and an unclogging of the criminal justice system. This paper does not attempt to calculate the costs and benefits of legalization. Rather, it suggests that if Prohibition is any guide, the cost to society from increased drug use is likely to be smaller than commonly believed.

⁵Recent estimates of the demand elasticity for alcohol vary greatly. For example, Cook and Tauchen estimate an elasticity of 1.8, while S. I. Ornstein and D. M. Hanssens (1985) estimate elasticities of .8 to 1.0 for spirits but only .1 for beer. In any event, the applicability of these figures here is questionable. These studies estimate local elasticities by considering tax changes. However, alcohol elasticities are unlikely to be constant over a wide range of prices and may have changed significantly over time. Furthermore, the above cited studies, in addition to having conflicting results, are plagued by the lack of reliable price data.

Who Uses Illegal Drugs?

By ROBIN SICKLES AND PAUL TAUBMAN*

In this paper we will use the *National Longitudinal Sample of Youth* (NLSY) to estimate a model of who uses various drugs and at what ages. Data already exist on who takes illegal drugs, but thus far the descriptive analysis has not utilized recently developed statistical frameworks that provide for more informative estimates.

I. Prior Literature

Gary Becker and Kevin Murphy (1988) present a theoretical model of rational addiction that requires information on past, present and future prices. They do not study illegal drugs empirically in this and their related papers.

A major data source is the annual survey of high school seniors (HSS), also known as "Monitoring the Future." This work is summarized in L. Johnston et al. (1988). They find a growing use of drugs (measured by monthly, annual, and lifetime prevalence) over time, and differences by region and sex. Cocaine use showed marked increases from 1976, though this levelled off from 1986 to 1987. They often rely on cross-tabs that leaves many variables uncontrolled and the results subject to omitted variable bias.

J. Bachman et al. (1984) use ordinary least squares (OLS) regressions in which the drug use in the three years post-high school is related to various characteristics such as living arrangements. While an improvement over cross-tabs, OLS applied to categorical dependent variables yields inefficient estimates (see M. Nerlove and S. Press, 1973).

Johnston et al. used follow-up surveys of a subsample drawn from each cohort. They find the use of some drugs decline at older

ages, say 35, though they do not determine if the heavy users have died, dropped out of the sample, or have been rehabilitated.¹

The HSS's initial restriction to high school seniors removes about 30 percent of the population who drop out of high school perhaps because of taking drugs. Studies based on the National Institute of Drug Abuse (NIDA) sample of people 12 and older show some heavy drug use of people less than 17 years old. (See J. D. Miller et al., 1982, and NIDA, 1985.)

Richard Clayton (1985) using the 1980 HSS presents univariate regressions that shows the frequency of use of cocaine is positively related to lifetime marijuana use and days out of school in the past month, but negatively related to high school grade point average. H. Abelson and Miller (1985), using the NIDA surveys covering 1974–82, show differences in the percentage using cocaine by education and race—for lifetime, 12 months, and last month measures. They find strong trends.

D. Kandel (1980) presents a recent survey of drinking and drug use among youth. People in their late 30's "mature out" of heroin use rather than die.

II. The Model

We assume that individuals maximize a utility function that has, as its arguments, various types of consumption and leisure. Note that some of the C_i s may affect utility by their impact on health in the utility function.

The choices of the level of the various consumption goods and leisure are subject to a budget constraint and a health production function. The health production function relates the stock or level of health to

*Rice University, Houston, TX 77251 and NBER, and University of Pennsylvania, Philadelphia, PA 19104 and NBER, respectively. We thank Craig Strain for his valuable research assistance.

¹The rehabilitation literature as in J. F. Maddux and D. P. Desmond (1986) is not very encouraging on this score.

a person's endowments (E) and some of the C_i .

The constrained maximization of utility leads to demand functions for each of the C_i including drugs which will depend on the wage rate, endowments, prices, and tastes. We allow tastes to vary by socioeconomic status such as education, family background, marital status, and age. Family background measures will include parental education and religious preference. We do not include recently obtained prices at this stage of our study and thus the interpretation of our results as indicative of demand behaviors rests on the strong assumptions of highly price inelastic demand behavior.

The National Longitudinal Survey (NLS) contains several random samples of men and women in various age groups. Data on drug use have been collected in the youth segment, which started in 1979, in two time periods—1984 and 1988. Date of first use of various drugs is also available. For each sample, interviews have been conducted over time on many variables other than drugs.

This sample has drug use information measured over the last month, last year, and lifetime, and also amount used for a number of specific drugs including amphetamines, barbituates, heroin, and cocaine. We study separately marijuana, a combination of marijuana, cocaine, and all other drugs (including about 55 cases of barbituate use), and no drug use during the last 12 months. (Most of the hard drug observations are for cocaine.)

Self-Reported Drug Data Accuracy. Our sample uses surveys in which people are asked if they have taken various illegal drugs. Will such questions elicit valid and reliable information? Zili Amsel et al. (1976) concluded that such self-reported drug use data were fairly accurate using a sample of 829 addicts under treatment.

Johnston et al. used several waves of responses to the drug use questions in "Monitoring The Future," and conclude that either people lie consistently over time or provide reasonably accurate answers. They state: "Like most studies dealing with sensitive behaviors, we have no direct, objective

validation of the present measures; however, the considerable amount of inferential evidence that exists strongly suggests that the self-report questions produce largely valid data" (p. 20). Moreover, a majority of seniors, and up to 80 percent of the subsequent subsample, report taking drugs.

E. Wish (1987) studied men recently arrested and held in the Manhattan Central Booking in 1984. About 95 percent of those approached agreed to an interview and 84 percent of these gave a urine specimen. The interview data yielded substantially smaller drug use than the urine specimens (for cocaine in 1986, 43 vs. 82 percent), but as Wish notes, the circumstances are not conducive to honesty.

B. S. Mensch and D. B. Kandel (1988) argue that *NLS* drug use reports are too low because of shame associated with admitting to partaking in an immoral activity to an interviewer whom you see annually. However, the head of the *NLS*, R. Olsen, has informed us of an unpublished study in which half the respondents were asked the questions by the interviewer and half were given a questionnaire to mail back. The drug use estimates were the same via the two methods, but the mailed-back questionnaire reported significantly more abortions.

Statistical Methods. Prior research has generally used estimates based on means for various groups or on OLS regressions. Using means for various groups is only useful if all cells have large numbers of observations, but available data sets are too small to allow for more than a few characteristics in defining a cell. The linear probability model has a number of statistical problems (G. S. Maddala, 1983).

We allow the demand response, Y , of an individual unit to be restricted to one of a number, say $k + 1$ ($k \geq 1$), of ordinal values, denoted for convenience by $1, \dots, k, k + 1$. Using the LOGISTIC model in "SAS," we fit a parallel lines regression model based on the cumulative distribution probabilities of the response categories, rather than on their individual probabilities. The model has the form

$$g(\Pr(Y \leq i|x)) = \alpha_i + \beta'x, \quad 1 \leq i \leq k$$

where $\alpha_1, \dots, \alpha_k$ are k intercept parameters, and β is the vector of slope parameters.

The logit function $g(\rho) = \log(\rho/(1-\rho))$ is the inverse of the cumulative logistic distribution function, which is $F(x) = 1/(1 + \exp(-x))$.

Suppose the response variable can take on the ordered values $1, \dots, k, k+1$. The probability that the j th observation has response i is given by

$$\Pr(Y_j = i | x_j) = \begin{cases} F(\alpha_1 + \beta'x_j) & i = 1 \\ F(\alpha_i + \beta'x_j) - F(\alpha_{i-1} + \beta'x_j) & 1 < i \leq k \\ 1 - F(\alpha_k + \beta'x_j) & i = k+1 \end{cases}$$

In our estimates we have included an estimate of each individuals' fixed effect obtained from a Tobit estimate of a wage equation estimated over the period 1979-83. Here we use the independent variables in Tables 1 and 2 and family income. (Results from other specifications that alter the num-

ber of demand categories and the distribution of latent demand are available on request.) We average the residuals over time for each individual. (We used the inverse of the Mills ratio to correct for selectivity.) This estimated fixed effect is denoted as FE .

III. Results

We have calculated means and standard deviations in 1984 and 1988. We code drug use as in the last year: no use (about 30 percent in both years), only marijuana (about 35 and 30 percent in 1984 and 1988, respectively), and marijuana and other drugs, mostly cocaine. (Means for other variables are given in the Appendix, available on request.)

Tables 1 and 2 present our main findings based on ordered logits (ranging from no use = 0 to marijuana plus cocaine = 2). *MGRADE* and *FGRADE* are years of education of the mother and father and the religious preference dummies are Catholic, no religion, and Baptist. Other variable names are obvious. In 1984, all variables are statistically significant except income in

1984 and belonging to the baptist religion. Taking account of the ordering scale, use of drugs decreases with education of self and parents, wage fixed effects, and being Catholic or no religious preference. There are increases with being black or female.

In 1988 the sign and significance patterns are the same though AGE is now of marginal significance. The 1988 coefficients are generally of smaller size in absolute value.

The relative probability of moving from no drug use to moderate drug use in 1984 is equal to 11.6 times the coefficients shown in Table 1. For example, blacks are 400 percent more likely to make this move. The movement to hard drugs from the no use category is 3.2 times the coefficient or about 120 percent for blacks. (Calculated at the means for all other variables.) There are both bigger and smaller effects for other variables.

In both years, we have examined the results on other coefficients of dropping the wage fixed effects variable. Some of the coefficients such as black and income change greatly.

There are many significant effects of sociodemographic variables on drug use. The results seem stable over our two time periods. Estimates of income fixed effects are quite important with people who earn more using drugs more, though the wage fixed effects are weaker in 1988.

MARKET STRUCTURE AND THE EMERGENCE OF NEW TECHNOLOGIES

R&D Competition for Product Innovation: An Endless Race

By REIKO AOKI*

The purpose of this paper is to explain industry dynamics through the innovative activity of firms. In research-intensive industries, such as pharmaceuticals and high-technology electronics, the constant introduction of new products and the R&D investment to achieve product innovation is critical for the survival of a firm. In such an environment, firms invest in R&D not only to gain immediate profit by selling successful products, but also to maintain the level of their R&D technology or knowledge. A firm's R&D behavior is based on dynamic considerations and this behavior itself will generate the dynamics of the market. In recent years, many traditionally static oligopoly concepts, such as pricing, quantity and investment decisions, have been applied to analysis of industry dynamics in the form of dynamic stochastic games (Lloyd Shapley, 1953). I take a similar approach by extending the patent race models to examine market dynamics. Here the rivalry among firms in an industry continues over many sequences of products and may potentially last forever. There is no predetermined goal or end of the race.

I consider one basic model with two variations. All three are dynamic games with infinitely many discrete periods. In the basic model, a firm's R&D technology is deterministic. Investment always results in progress by one step. Although this is the only model here that is sufficiently tractable for explicit characterization of equilibrium strategies, the system's equilibrium dynam-

ics are limited. In the second model, a stochastic R&D technology is considered. The firm's investment either advances its state of knowledge by one step or leaves it where it was. In the third model, I modify the stochastic R&D so that a firm may advance more than one step. This means that a firm may jump from being a follower to being a leader in one period, without ever being in a tie, that is, a firm may leapfrog (Drew Fudenberg et al., 1983).

In the first model, with deterministic R&D technology, almost all states are absorbing. That is, once those states are reached, the market never changes to another state. The industry evolution literature predicts that asymptotically, the economy converges to concentration or dominance of a single firm. In this model, depending on the initial state of the economy, the economy may asymptotically consist either of multiple firms competing vigorously forever or of just one dominant firm. Also, no matter how low the R&D cost, the industry leader's lead is never large because the follower will drop out when the leader's lead is still small. The introduction of a stochastic element in the second model eliminates the perfect predictability that prevents firms from competing. Although the probability of failure may discourage investment, the positive probability that the leader may fail to make progress causes the follower to remain in the competition for larger leads by the leader. If leapfrogging is possible, the lead may be even greater before the follower drops out. However, even with leapfrogging, the positive cost of investment causes the follower to drop out if the lead becomes too great. Once the follower leaves, the leader stops investing and the game effectively terminates. Thus there is an en-

*Department of Economics, State University of New York, Stony Brook, NY 11794-4384. I am grateful to Beth Allen for her comments that have vastly improved the paper as well as my understanding. I also thank John Hillas for comments.

dogenous end to the game that is reached with probability one and always ends with one dominant firm.

1. The Basic Model

Consider two firms of equal R&D efficiency engaged in R&D competition for an infinite number of periods. During each period, a firm either makes a R&D investment at cost c to advance its state of knowledge by one step, or does not invest anything and remains where it is. Initially, we consider a case where advancement is certain. The firm at the frontier of knowledge sells the current product. New products make previous products completely obsolete so that the firm at the frontier, or the leader during that period, is a monopolist and gets monopoly profit π^m . The follower obtains nothing for the period. If two firms are at the same level of knowledge, products coexist and each firm receives the duopoly profit π^d as its profit for the period. A firm's instantaneous payoff for the period is the profit less investment cost, if any. Investment decisions maximize the discounted sum of instantaneous payoffs given the rival's investment decision. Even with zero profit in the current period, investment may be undertaken in order to improve the state of knowledge which affects future profit prospects.

It is assumed there are no diminishing returns to investment and thus the cost c of investment is independent of the state of knowledge. Profits depend only on the market structure (duopoly or monopoly) and are independent of the size of the lead. These two factors mean that only the *relative* positions matter to the firms and all possible payoff relevant positions of firms (states of the game) can be summarized by the set of integers. The integer k represents the lead of firm 1. If $k < 0$ then firm 2 is the leader, while $k = 0$ means that the two firms are even. Simultaneous investment by firm 1 and no investment by firm 2 increases k by one. If both firms invest, k remains the same since they both advance by one step and their relative position is unchanged. Note also that an infinite sequence of not

investing by the follower is effectively dropping out. The firm then obtains zero profits and expenditure equal zero perpetually, as if firm were no longer competing.

Let us consider an equilibrium in symmetric stationary Markov strategies. A strategy is completely described by specifying the action of each firm at each state k . I use $r^i(k) \in [0, 1]$ to denote the probability of firm i investing at state k . If $r^i(k) = 0$, firm i does not invest, if $r^i(k) = 1$, it does invest, and if $0 < r^i(k) < 1$, firm i plays a mixed strategy at state k . A firm's decision as to what action to take at each state depends only on that state, independent of history up to that point (Markov) and the period in which that state is reached (stationarity). Equilibrium strategies consist of actions that are best responses of each firm given its rival's equilibrium strategy. Thus they are subgame perfect Nash equilibria. For exposition, I focus on states in which firm 1 is at least as advanced as firm 2, that is, on nonnegative values of k (symmetry). An equilibrium associates a pair $(v^1(k), v^2(k))$ to each state k . These are the continuation values of the game and equal the expected discounted sum of instantaneous payoffs when firms invest according to the equilibrium strategies.

The properties of equilibrium differ according to the magnitude of costs relative to profits (see my 1990 paper). First, if cost is high, ($c > (\pi^m - \pi^d)/(1 - \beta)$, where β is the discount factor), neither the leader nor the follower ever invests. The follower does not invest even when it is only one step behind since the stream of profits after getting even is not enough to justify the cost. Because the monopoly profit does not depend on the size of the lead, the leader has no incentive to invest when the follower does not invest. Nor do tied firms invest. The cost is so high that a firm would not choose to take the lead and obtain an infinite sequence of monopoly profits instead of duopoly profits. Thus in an industry where R&D costs are high relative to profit, there is no innovative activity.

On the other hand, if cost is low ($c < \pi^d$), both firms invest when they are even. The value of catching up is less attractive for the

follower and it will drop out even when the lead is small despite the small investment costs. In fact, investment continues only when the follower is one step behind, and at this point the follower is indifferent between investing and not investing. Thus the continuation value for the follower is zero and when he is two or more steps behind, he will not choose to invest—at two or more steps behind, he chooses not to invest as a best response to a leader who is not investing. This is effectively dropping out. When the follower is one step behind, it invests with probability less than one because the low cost means that the leader will invest as a best response to the follower investing. Thus at $k = 1$, firms will play mixed strategies. When the cost is slightly higher (so that it is between the two previous cases), a firm will invest only if the rival does not invest at $k = 0$. Thus, equilibrium differs based on behavior at $k = 0$: neither firm invests, only one firm invests, and both invest, according to the size of investment cost. In all three cases, the follower does not invest at all when it is one or more steps behind ($r^1(k) = r^2(k) = 0, \forall k \geq 1$).

The results of deterministic R&D technology must be interpreted with care. For instance, the case of small cost had an equilibrium of the form $r^1(0) = r^2(0) = 1, 0 < r^1(1) < r^2(1) < 1, r^1(k) = r^2(k) = 0 \forall k \geq 2$. This means that if the economy starts with both firms at the same level, it stays that way forever. States $k \geq 1$ are never reached. If the initial state is $k = 1$, the transition law is stochastic, and with positive probability, the follower may catch up (in which case again both firms invest forever and the two firms stay at that state forever). The leader may also increase the lead to two steps ($k = 2$), in which case the follower ceases to invest and the leader enjoys monopoly profits forever. Similarly, for intermediate cost values, all states except $k = 0$ are absorbing states. Lack of transition from state to state in equilibrium is due to several factors: deterministic technology, zero instantaneous payoff of the follower and the stationarity of strategies.

The remainder of the game is completely predictable except for the stochastic out-

come from mixed strategies. This eliminates a phenomenon such as a follower investing to narrow the lead if the leader ever invests when lead is narrower. If such behavior occurs in equilibrium, the follower knows that it can never get even, which is the first time it obtains positive instantaneous profit. Hence there is no incentive for any investment once it is the follower. Stationarity and zero payoff of the follower eliminates the possibility of returning to a state after several periods with probability one. Since costs must be incurred between the two periods, there is no way the continuation value could be the same, which should be the case for stationary Markov equilibrium. We will never have a situation where firms take turns being leaders and followers.

The deterministic model clarifies the effect of the magnitude of cost. One might expect low costs to accommodate the follower. However, low cost does not imply that the discounted expected sum of profits is high since vigorous competition dissipates profits. The follower still drops out after falling behind by only two steps.

II. A Simple Stochastic R&D Technology

In this section, I introduce uncertainty into the R&D technology. Instead of a firm advancing by one step with probability one when it invests c , stochastic R&D technology means that the advance takes place with probability $p \in (0, 1)$. Thus if both firms invest at state k , the state next period will be $k + 1$ with probability $p(1 - p)$, $k - 1$ with probability $p(1 - p)$ and will remain k with probability $p^2 + (1 - p)^2$. Everything else (instantaneous profits and strategies) remains the same. As with any dynamic stochastic model, the characterization of equilibrium is extremely difficult. One needs to solve both the maximization problem and the continuation value equation for the optimal strategies and continuation values simultaneously for both firms. Note that the action spaces are compact and convex, all instantaneous payoffs are bounded and there are only a countable number of states. Since firms are maximizing the sum of discounted expected payoffs, these condi-

tions guarantee the existence of stationary Markov equilibrium strategies by the standard fixed point arguments (for example, as in A. Federgruen, 1978). I do not attempt a full characterization of equilibrium (strategies and continuation values) here.

We are able to answer the following question: will the follower that is two or more steps behind try to catch up when the technology is stochastic? Stochastic R&D technologies eliminate the complete predictability which prevented the follower from trying to eliminate the lag in the deterministic model. Of course the follower's chance of successfully doing so is adversely affected by the R&D technology. On the other hand, with deterministic R&D, when the cost was low, the leader's best response to follower investing was to invest. However, with stochastic R&D, for the same range of cost, a leader may choose not to invest if the probability p of success is small. This is because the chance that the follower will not succeed in advancing reduces the leader's incentive, thereby favoring the follower. The net effect is that the follower becomes more aggressive for very low values of p , and will not drop out even after it is two steps behind, if cost is sufficiently small.

III. The Possibility of Leapfrogging

I now consider a stochastic R&D technology with leapfrogging (see my 1988 paper). The cost of investment is still constant c , but now a firm may advance by zero or any positive number of steps. Smaller advances are more likely than larger advances. As before, no investment means no advancement with probability one. All instantaneous profits and strategies remain the same.

As in the deterministic case, if c is small both firms will invest when the two firms are tied. There actually may be a range of small leads (small k 's) where both leader and the follower invest ($r^1(k) = r^2(k) = 1$). Again, since the monopoly profit does not depend on how many steps ahead the leader is, leader will never invest if the follower is not investing. Despite the possibility of leapfrogging, there are still leads large

enough for the follower to stop investing. Together with the preceding observation, this implies that there will be a maximum difference between leader and follower. With leads greater than the maximum, the follower will drop out and the game effectively ends. Thus if a firm is lucky and attains a very large lead, it will remain a monopolist forever without further effort.

The possibility of leapfrogging means that a follower this period has a positive probability of gaining a large enough lead next period to force the present leader out. This may cause the follower to continue investing even when the lead is two or more steps. On the other hand, the positive probability that the follower may not catch up may cause the leader to choose not to invest. Thus there may be a nonempty set of states where the follower invests with probability one ($r^2(k) = 1$) and the leader invests with probability zero ($r^1(k) = 0$). This also implies that the continuation value of the follower may not be monotonic, contrary to the deterministic model above and other patent race models (see Christopher Harris and John Vickers, 1987; Steve Lippman and Kevin McCardle, 1987). Consider a state \hat{k} where $r^2(\hat{k}) = 1$ and $r^1(\hat{k}) = 0$. The follower invests but the outcome of R&D is such that it remains a follower but now the lead k' is smaller, so that $r^1(k') = r^2(k') = 1$. Fixing the action of the leader, the follower would prefer to be at k' . However, the follower prefers the action of the leader at \hat{k} . It may be that this second effect dominates. The follower may find itself in a worse position at k' than at the larger \hat{k} with the continuation value smaller at k' than at \hat{k} . In this case there is a nonmonotonicity in the continuation value of firm 2. When k is very negative, firm 2 is a monopolist and the continuation value is at its maximum. As k increases, the continuation value decreases. However, the continuation value increases between k' and \hat{k} .

IV. Concluding Remarks

I have examined three different R&D technologies: deterministic, stochastic without leapfrogging, and stochastic with leap-

frogging. Although the deterministic model illuminates the relevant tradeoffs as well as the effects of R&D costs, in equilibrium there are almost no real dynamics. Initial states are almost always the asymptotic states as well. The lack of dynamics is partially due to the restriction to stationary Markov strategies. On the other hand, my results suggest that one explanation for a single firm's dominance in an industry is the deterministic nature of R&D. Success is possible with probability one to the follower as well as the leader, but the follower never tries to catch up because it knows the leader will then invest.

Even with single-step advances, stochastic R&D prolongs competition. That is, the follower may still continue to invest even when it is two steps behind. Uncertainty of success works to the follower's advantage by reducing the leader's incentive to invest when the follower is investing. The shortcoming of this approach is the difficulty of completely characterizing equilibrium. Leapfrogging facilitates the characterization because the set of possible states in the next period is larger from any state. In particular, there is always positive probability of entering states with positive instantaneous payoffs if a firm invests, even when it is the follower. In equilibrium, there will be actual transitions between various states, while monopoly with the follower inactive will be the only absorbing state.

There are a few simplifications I have made which are crucial to the results. Instantaneous profit is independent of how large the lead is. The state of knowledge of a firm would typically be reflected in the quality of product the firm sells. There are cases where the profit would depend not only on the *relative* quality but also on *absolute* quality. If that were the case, the leader would have an incentive to continue improving even after it has become a monopolist, but the result that the follower drops out

when the lead is too large still should be true. Moreover, with heterogeneous products or consumers, the follower's instantaneous profit may be positive. This would give the follower an incentive to continue investing even when it is far behind, so that it may not ever drop out.

Although there is exit by a firm in my model, there is no entry. The lack of possibility of entry allows the leader to be a monopolist forever without any investment in technology. In the stochastic models, monopoly with the follower inactive is the only absorbing state and asymptotically the market becomes a monopoly with probability one. Yet, to describe industry evolution, entry should be considered. Otherwise, one firm dominance occurs almost by definition.

Choosing R&D Projects: An Informational Approach

By BETH ALLEN*

This paper argues that research and development (R&D) should be viewed explicitly as information acquisition activities. A firm's choice among various R&D strategies is equivalent to deciding what information to gather. Moreover, the pursuit of different research projects involves searching for different sorts of information.

Thus, R&D is not homogeneous. To attempt to summarize R&D activities by a single aggregate measure (for example, by the cost of R&D inputs or by modeling the intensity of only a single exogenously given project) is inherently misleading. Such a story misses the important possibilities for alternative R&D projects to serve as complements or substitutes for each other. The neglect of heterogeneity risks misleading conclusions about welfare effects based on underinvestment or overinvestment in research and development.

This paper proposes an alternative abstract analysis of R&D activities that focuses on filling the gaps discussed above. I suggest that the successful outcomes of projects can be specified by differentiated information. Each project thus is represented by a probability of success (or an arrival rate for the dynamic version of our model) as well as a description of the knowledge that may be acquired. This formulation facilitates the comparison of projects in terms of substitution, complementarities, and dominance relationships (where one project dominates another if it yields superior infor-

mation with at least the same success rate or equivalent information with a strictly larger probability or arrival rate).

Despite the preceding observations, the literature emphasizes homogeneous or aggregate R&D activity. An exception is provided by the portfolio choice analogy of Sudipto Bhattacharya and Dilip Mookherjee (1986). They permit different risk profiles when different research methods are employed to search for the same discovery. The informational content of all successful projects is the same; only their riskiness differs. The authors analyze the effects of mean-preserving spreads and correlation on the choice of privately and socially optimal R&D investment decisions with risk aversion. Kenneth Judd (1986) analyzes a multi-stage game in which firms choose R&D portfolios. Partha Dasgupta and Eric Maskin (1987) consider a model in which each firm chooses to locate its research project in an interval of parameters. Dasgupta (1990) examines the choice of an endogenous (finite) number of independent and identical "parallel" projects. Finally, Richard Nelson (1982) discusses complementarities among projects and externalities from research to development; an endogenous (finite) number of parallel research projects are undertaken followed by development of the best project.

I. A Model of Heterogeneous R&D Projects

This section summarizes a microeconomic model of stochastic information acquisition as a result of alternative R&D activities. At this point, before any notation is introduced, clarification is needed for the fundamental concepts of information, R&D projects, and success. Information (sometimes termed an information structure for emphasis) is a generalized partition of states of the world. Here information is an *ex ante* concept (i.e., the ability to know that the true

*Milton C. Denbo Term Professor of Economics, University of Pennsylvania, Philadelphia, PA 19104-6297. This research was supported by NSF grant No. SES88-21442. I thank the participants, especially Reiko Aoki, in the Industrial Organization Program (organized by Suzanne Scotchmer and Yair Tauman) of the 1990 Stony Brook Summer Institute on Game Theory and Economics for helping to educate me about the recent R&D literature. Pamela Brown and Tara Vishwanath provided helpful comments on the preliminary version of this paper.

state of the world lies in one of the subsets defining the partition) rather than the *ex post* fact that the true state actually lies in a certain subset. Success means that such an information structure is acquired and can be used to condition future economic decisions. An R&D project is defined to be an attempt to obtain access to a particular information structure. Specification of a project and its intensity yields a success rate, either in the form of the probability of success or an arrival rate for success.

Perhaps an analogy with research in economics would be useful. Let us begin with a specific question (think of this as the information we wish to obtain), such as whether a class of models has an equilibrium. Success is interpreted as the completion of this piece of economic research. For instance, we find a counterexample to the existence of equilibrium, we prove that equilibria exist, or we find additional (necessary) conditions (for example, strictly concave and twice continuously differentiable utilities) under which we can demonstrate that there is an equilibrium. Notice that success could involve any of these three definite outcomes or sets in the partition. In particular, discovery of a counterexample constitutes success, while lack of success means that we have been unable to reach any clear conclusion about the equilibrium problem for our class of models. Finally, in this context, a research project is determined by the selection of an open question and an "intensity" of research (which would, in fact, correspond to the difficulty of the various methods of attack that we examine). When a project succeeds, we clearly stop working on that particular project, although we may or may not (i.e., if the result is an uninteresting counterexample) publish the results.

To return to the formal model, let Ω be the set of states of the world, and think of Ω as sufficiently large to incorporate all of the economically relevant uncertainty except the random success or failure of research projects.¹ Typical states of the world will be denoted $\omega \in \Omega$. A measurable event

is a subset of Ω that economic agents "eventually learn." Let \mathcal{F} be the σ -field of measurable events. Then define a probability measure μ on the measurable space (Ω, \mathcal{F}) so that the abstract probability space $(\Omega, \mathcal{F}, \mu)$ summarizes all of the uncertainty in the world except project successes. An interpretation is that knowledge of ω (or of an event in \mathcal{F}) tells us all of the technologies that could ever be discovered.

As indicated earlier, information is taken to be a generalized partition (defined by subsets in \mathcal{F}) of Ω . Formally, an information structure is a complete sub- σ -field of \mathcal{F} .² Let \mathcal{F}^* denote the set of complete sub- σ -fields of \mathcal{F} and make \mathcal{F}^* into a metric space via the distance function

$$d(G, H) = \sup_{G \in \mathcal{G}} \inf_{H \in \mathcal{H}} \mu(G \Delta H) \\ + \sup_{H \in \mathcal{H}} \inf_{G \in \mathcal{G}} \mu(G \Delta H)$$

where \mathcal{G} and \mathcal{H} belong to \mathcal{F}^* and, for $G \in \mathcal{F}$ and $H \in \mathcal{F}$, $G \Delta H = (G \cup H) \setminus (G \cap H)$ is their symmetric difference. (See my 1990 paper and the references listed there for details.) The set \mathcal{F}^* of information structures represents all possible research questions.

To define R&D projects, we must also specify their intensities (interpreted as summary measures of the research methodology in terms of its corresponding costs). This is done by associating a nonnegative number with an information structure. Hence the ordered pair (G, c) , where $G \in \mathcal{F}^*$ and $c \in \mathbb{R}_+$, denotes a research project. Generalization of the model to dynamic R&D projects in which the intensities vary over time is obvious.

Uncertain R&D projects require also that success rates be added to the model. These success rates are completely specified by the research project; that is, by the choice of an information structure and its intensity. To

¹Later I discuss the removal of this qualification.

²This is needed so that if the distance between two information structures is zero, then they are the same. A complete σ -field is one that contains all subsets of sets of measure zero. Of course, we also need completeness of \mathcal{F} .

simplify some mathematical technicalities, I shall assume independence (for now) and ignore the measurability problem. Thus, write $\pi: \mathbf{F}^* \times \mathbb{R}_+ \rightarrow [0, 1]$ for the success rate of an R&D project in the static version of the model, where $\pi(\mathbf{G}, c)$ gives the probability that project (\mathbf{G}, c) succeeds. In the dynamic model, let $\lambda: \mathbf{F}^* \times \mathbb{R}_+ \rightarrow [0, 1]$ give the (Poisson) arrival rate for success, where $\lambda(\mathbf{G}, c)$ defines the success arrival rate of project (\mathbf{G}, c) . I assume that all economic agents know the success rates or success arrival rates of all R&D projects.³

The value of a project is the amount by which its expected rewards W exceed its cost c . For the static model, write the value function V as

$$V(\mathbf{G}, c; \pi(\mathbf{G}, c)) = \pi(\mathbf{G}, c)W(\mathbf{G}) - c$$

while, in the discrete time dynamic model, the value V_t at time t is

$$\begin{aligned} V_t(\mathbf{G}, c; \lambda(\mathbf{G}, c)) \\ = w_t(\mathbf{G})\Pr\{\text{success at or before } t | \lambda(\mathbf{G}, c)\} \\ - c \Pr\{\text{no success before } t | \lambda(\mathbf{G}, c)\} \end{aligned}$$

where $w_t(\mathbf{G})$ denotes the project's expected return (if successful) in period t ,⁴ so that the expected discounted net present value (with discount rate δ) is

$$\begin{aligned} V_\delta(\mathbf{G}, c; \lambda(\mathbf{G}, c)) \\ = \sum_{t=1}^{\infty} \delta^t w_t(\mathbf{G}) \Pr\{\text{success at or before } t | \lambda(\mathbf{G}, c)\} \\ - \sum_{t=1}^{\infty} \delta^t c \Pr\{\text{no success before } t | \lambda(\mathbf{G}, c)\} \end{aligned}$$

³If this is not satisfied, then the two-armed bandit problem may arise and firms could choose strictly dominated projects infinitely often. See, for instance, Michael Rothschild (1974).

⁴ $w_t(\mathbf{G})$ could depend on t if, for example, population growth affects the size of the market for the innovation.

or, alternatively, if t^* denotes the random time at which success occurs,

$$\begin{aligned} V_\delta(\mathbf{G}, c; \lambda(\mathbf{G}, c)) \\ = E_{t^*} \left[\sum_{t=t^*}^{\infty} \delta^t w_t(\mathbf{G}) - \sum_{t=1}^{t^*} \delta^t c \right]. \end{aligned}$$

Observe that it is assumed that costs are paid during every period up to and including the time when success occurs (or the discovery "arrives"). The formulae for the dynamic case could easily be modified to permit a sequence of discoveries, so that a finite or infinite sequence of increasing information σ -fields arrive at dates given by a sequence of random times.

Since additional information can always be ignored by the firm, the reward functions are nondecreasing; that is, if $\mathbf{G} \supseteq \mathbf{H}$, then $W(\mathbf{G}) \geq W(\mathbf{H})$ and $w_t(\mathbf{G}) \geq w_t(\mathbf{H})$. This implies that we have $V(\mathbf{G}, c; \pi(\mathbf{G}, c)) \geq V(\mathbf{H}, c; \pi(\mathbf{H}, c))$ whenever $\mathbf{G} \supseteq \mathbf{H}$ and $\pi(\mathbf{G}, c) \geq \pi(\mathbf{H}, c)$. Moreover, for the dynamic case, $\mathbf{G} \supseteq \mathbf{H}$ implies $V_t(\mathbf{G}, c; \lambda) \geq V_t(\mathbf{H}, c; \lambda)$ and $V_\delta(\mathbf{G}, c; \lambda) \geq V_\delta(\mathbf{H}, c; \lambda)$.

I assume that the value functions are jointly continuous in their arguments. This is innocuous when information is used to maximize a conditional expectation and/or when information structures determine the firm's production function in a continuous way. (See my 1983 article for a formal statement and proof.) On the other hand, concavity cannot hold because our underlying set of information structures does not have the structure of a convex set.

Finally, note that the success rate π and success arrival rate λ specifications above implicitly assume that the outcome of each project undertaken by a firm does not depend on the other R&D projects in the profile chosen by the firm. Moreover, success was assumed to be independent of the underlying basic state of the world, $\omega \in \Omega$. At the expense of more complicated notation and additional mathematical difficulties, we could incorporate R&D project successes into the description of the set Ω of states of the world. Then a generalized random variable defined on Ω would indicate which projects would succeed if they were

to be performed. Similarly, we could define our success random variable so that it depends on the entire set of R&D projects that are actually undertaken.

II. The Firm's Choice Problem

Assume either that the firm is risk neutral (so that it maximizes expected profits) or risk averse with a utility function (defined over profits) that is continuous, increasing, and concave. Then the firm's optimal (static or dynamic) choice of a single R&D project among a compact set of projects is well defined, but need not be unique; maximizers exist but ties may occur.

If the firm's possibilities are expanded to encompass the selection of several projects that may serve as complements or substitutes for each other (think of competing research teams within the firm), a generalization of the firm's choice set from projects to (finite and bounded) sets of projects is needed.⁵ To do this, represent each project by the probability measure that assigns mass one to it. A profile or portfolio of projects is given by a finite sum of such probabilities. This method yields a compact choice set so that the maximum theorem applies (because the firm's objective function depends continuously on research profiles). (Technical details are in my 1986 paper.)

III. Strategic Interaction

Section II considered the behavior of a single firm in its choice among R&D activities. Here I wish to permit strategic interaction among competing firms. The natural way to do this is to analyze the noncooperative game among firms in which strategies are sets of projects.

Unfortunately, whenever firms choose among R&D projects (even if they are restricted to finitely many alternative projects), the game does not generally have a Nash equilibrium in pure strategies. With a finite

number of pure strategies, convexity of (pure) strategy sets fails, but the problem may be solved by resorting to mixed strategies. For the choice problem involving (bounded) profiles of R&D projects (from an arbitrary compact set of information structures) described earlier, again the extension to mixed strategies restores convexity of strategy sets and best-reply correspondences. The usual problems arise here in the interpretation of mixed strategies. Perhaps the best story in this context is to imagine each firm optimizing against its probabilistic beliefs about other firms' behaviors.

Continuous dependence of payoffs on the strategy choices of other firms can be derived from the stochastic nature of R&D success. In other words, appropriate choices of the π and λ functions yield expected payoffs which exhibit continuity in the (pure or mixed) strategy profiles of all firms.

IV. Welfare Consequences

For the important issue of whether underinvestment or overinvestment in research and development occurs, the hypothesis of homogeneous R&D is especially troublesome. The classical literature (i.e., Kenneth Arrow, 1962, and Jack Hirshleifer, 1971), as well as more contemporary treatments, analyzes the problem by comparing the actual level of R&D investment with the socially optimal amount of aggregate information acquisition activities.

If every project yields exactly the same innovation when it succeeds, patent races tend to create excessive waste. On the other hand, duplication of effort is unlikely to be socially suboptimal if firms pursue distinct projects or if intermediate discoveries can be shared. Yet these aspects can be explicitly modeled only when differentiated information is incorporated.

For spillovers, a similar problem arises. A spillover frequently takes the form of information obtained from a research project oriented to one purpose that can then be joined together with additional information from another research project undertaken by a different firm. Consequently, the com-

⁵For the multi-armed bandit problem with parallel projects, Tara Vishwanath (1990) shows that the number and type of projects chosen may change over time.

bination is utilized for a different purpose. Such an analysis demands that different types of R&D projects be explicitly considered.

Finally, the recent public policy discussions of cooperative R&D ventures provide another example where heterogeneity of information is relevant for welfare conclusions. Surely the most interesting cases of potentially beneficial cooperation are based on economies of scope and specialized expertise of participants. These factors may be fully included in the analysis only when appropriately described differentiated R&D projects constitute allowable strategies.

The Determinants of Investment in New Technology

By SARAH J. LANE*

New technologies displace older methods and lead to improvements in productivity. Since the decision to invest in a new technology depends on the costs and benefits of adoption, the use of new technologies will not be uniform across either technologies, adopters, or time. This paper extends the previous literature on the diffusion of new technology by examining the effect of the structure of the output market and the effect of investment in earlier competing technologies on the decision to adopt. The case studied in detail is the use of continuous mining machinery in underground bituminous coal mining.

Neoclassical models assume that the integrated firm has the authority to make employment, production, distribution, and investment decisions for all divisions of the firm. As a result, vertical integration may alter control over decision making, and a vertically integrated firm may have different rates of technological adoption. Indeed, I find that vertical integration is an important determinant of the rate of adoption. I also conclude that the installed base of earlier competing technologies affects the adoption of new technology.

Bituminous coal mining in the United States is well suited for such a study since the market structure of the coal mining industry has large variation; along with thousands of very small producers, there are a number of large producers. In addition, there is also variation in the structure of the output market, since a subset of mines are integrated with their consumers such as steel companies or electric utility companies.

Like E. Mansfield (1961), this paper looks at the costs and benefits of the introduction

of a new technology. It differs from previous work by estimating a stock-adjustment model so as to take advantage of the state-level panel data and to allow for shifts in the rate of adoption over time.

I. Coal Mining in the United States: 1945-75

The trends in production have been a movement towards the West from the East and towards surface from underground mining. Only those states with a significant portion of underground production are included in the study (Alabama, Colorado, Illinois, Indiana, Kentucky, Maryland, Ohio, Pennsylvania, Tennessee, Utah, Virginia, and West Virginia.)

Underground mining operations consist of cutting, drilling, blasting, loading, and hauling the coal. Traditionally, these procedures were carried out in separate, sequential operations. Innovation began with the mechanization and improvement of each step in sequence to eliminate successive bottlenecks. More recent innovations, such as continuous mining machines and longwall mining machines, integrated the separate steps of the coal mining process. In continuous mining, a rotating head digs into the coal seam, removes the coal, and then transfers it to a conveyor for transport out of the mine. Coal was mined using this method beginning after World War II, and accounted for over 50 percent of coal output by the 1970's. Longwall mining machines added roof supports but have not been widely introduced. Since continuous mining machines replace a sequence of machines, the installed base of competing technology would be expected to affect the adoption of the new innovation.¹

*Assistant Professor, School of Management, Boston University, Boston, MA 02215. I thank Greg Clark, Zvi Griliches, Joyce Jacobsen, Leslie Papke, Robin Prager, Joshua Rosenbloom, and John Strudwick. John Pencavel provided access to part of the data. Boston University provided funding for the collection of additional data.

¹For example, G. E. Hale (1970), suggests that Consolidation Mine was slow in adopting the continuous miner partly because it had already modernized its digging and loading facilities with less advanced devices.

Sales of coal can take place in the open market or in the captive market. Captive production is that portion of production that is sold to or transferred to the parent company or a subsidiary of the parent company. The share of captive coal has been very stable over time at 16–17 percent on average. Illinois, Indiana, Maryland, Tennessee, and West Virginia have very low levels of captive production (approximately 2 percent), while Alabama, Pennsylvania, and Utah have high levels (approximately 40 percent).

If vertical integration does indeed alter decision making, the expected direction of the effect would be to increase the rate of adoption. As suggested by the literature, the vertically integrated firm may have a more stable demand. The development of a mine requires investment in mine-specific assets. Optimal technology is chosen to meet expected demand, and if that demand is more certain, as in the case of vertical integration, then innovation may be more likely.²

II. The Empirical Framework

Diffusion of an adoption is based on a decision to invest in new technology. Given this connection between investment and diffusion, the approach used is to estimate a basic stock-adjustment model where the proportion of production using the new technology approaches the desired proportion at some rate β .

$$(1) \quad \delta Pr_{it} / \delta t = \beta_{it} (Pd_{it} - Pr_{it-1}) \\ = \beta_{it} Pd_{it} - \beta_{it} Pr_{it-1},$$

where Pr_{it} is the proportion of output in state i at time t using the new technology, β_{it} is the rate of adjustment, and Pd_{it} is the desired proportion or "ceiling" level. Both the rate of adjustment and the desired proportion vary over time and across states.

²For example, consider this statement from ARCO: "In our underground mines... we have the opportunity to invest in an efficient longwall unit.... Our investment is contingent upon us securing long-term contracts, which we are currently negotiating" (p. 11, ARCO Security Analyst Meeting, March 20, 1990).

The variables that are expected to determine the ceiling reflect primarily technical constraints, and the variables that are expected to determine the rate reflect primarily economic constraints.

This stock-adjustment approach uses the full information available in the panel data set. Previous studies have used a logistic model that, because it places primary emphasis on the role of time in diffusion, assumes that potential adopters have an equal and time-invariant probability of adoption. The stock-adjustment model, in contrast, allows for shifts in the rate of adoption over time in response to changes in the economic costs and benefits of adoption.

I use the percentage of production using the new technology as the measure of adoption, since it is an accurate and unbiased measure of the production experience arising from the adoption decision. Since both mine size will vary and there will be a mix of technologies in any one mine, a measure based on the number of mines may severely over- or underestimate the coal mined using the new technology. For instance, by 1960, 47 percent of underground mines were using continuous mining machines, but the output mined using these machines accounted for only 27.7 percent of total underground production.

While the mine would be the ideal unit of analysis, only state-level data are available. Given this level of aggregation, entry and exit of mines will affect both the desired proportion of production using the new technology and the measured rate of adoption. An apparent increase in production will occur if the nonadopters are the older or marginal mines that eventually exit or fail. Similarly, an increase will occur if entering mines use the new technology and if adopters grow faster than nonadopters. This possible bias will exist with *any* adoption or diffusion measure when firms are entering or exiting the sample over the period. However, there is clearly economic content to the information that mines or firms that have not adopted are leaving the sample, and that firms entering the sample or growing faster are using the new technology. Therefore, the net change in the number of mines is included as an explanatory variable

TABLE 1—EXPLANATORY VARIABLES^a

	Ceiling	Rate	
A. Data that vary with both state and time are			
<i>AVGM</i>	(+)	(+)	Average underground mine size (in millions of tons)
<i>CMPM</i>	(-)		Number of cutting machines per mine
<i>MLN</i>	(-)		Proportion of underground production mined using mechanical loading machines ^b
<i>NUMMP</i>		(+)	Percentage change in the number of underground mines
<i>NSOMP</i>		(+)	Percentage of production not sold on the open market
<i>RESM</i>	(+)		Reserves per mine (total reserves of state in millions of tons/number of mines) ^c
<i>SW</i>	(+)		Average seam width ^c
B. Data that vary over time but not by state are			
<i>STOCK</i>		(-)	Total stock of coal in the economy (in millions of tons)
<i>WAGES</i>		(+)	Hourly wage in bituminous coal mining deflated by the CPI
<i>TIME</i>		(+)	Time trend

^aExpected signs are shown in parentheses.

^bSince the data on mechanical loading include production loaded by continuous mining machines, this variable is calculated as the percentage of production mechanically loaded minus the percentage of production mined by continuous mining machines.

^cFor these variables, data are not available for all years. The closest preceding year's data were used when observations were missing.

(gross data are not available). All the explanatory variables are defined in Table 1.

A measure of mine size is included since there is a greater probability that large mines will need to replace older equipment at any point in time. In addition, large mines are likely to have a wider range of operating conditions, making it more likely that they have a set of economic and geological conditions suitable for the new technology. Finally, there may be some minimum efficient mine size for the new technology.

Coal reserves are the stocks in situ, and are defined in terms of the short-term economic feasibility of extraction. Since there will be some minimum amount of reserves

necessary to justify the cost of the machines, reserves will negatively affect the ceiling. The width of seams is a measure of the feasibility and ease of introducing continuous mining. Continuous mining machines use less, though possibly more highly skilled labor. The net effect of an increase in wages should increase the rate of adoption if the labor-saving effect outweighs the skill effect. An increase in stocks which decreases the expected near term future price has a negative expected effect.

Finally, I include a time trend to capture all the time-varying variables that do not differ by state. Time also captures the effect of decreased uncertainty about the reliability and costs of using the new technology from observing earlier adopters. It should therefore have a positive coefficient if this effect is dominant.

III. Results and Conclusions

While the logistic model does not reveal much information about the underlying forces affecting the adoption decision, it does summarize the time-series of adoption. A logistic model estimated by state fits the data reasonably well for all states except Alabama and Indiana.³ In these states, after an initial period of an increase, production using this method drops dramatically as mines exit. Using the logistic estimates to calculate the year at which 50 percent of production is mined using continuous mining machines, I find that the three earliest adopters are also states that have relatively high levels of captive production. A similar though less pronounced pattern exists for the slower adopters. These results suggest that the state variation in captive sales is potentially an important determinant of the adoption of continuous mining machines.

Table 2 presents results for the stock-adjustment model estimated using the panel data. The estimation is a nonlinear function of the explanatory variables since the rate interacts with the ceiling proportion. The

³A more detailed version of this paper, available from the author, contains the estimates for the logistic.

full set of data is available for the years 1955–66 and 1968–74.

Only average mine size is (marginally) significant in the specification that sets the ceiling proportion constant at 100 (col. 1). Allowing the ceiling to vary (cols. 2 and 3) improves the estimation. Whenever *MLN* is excluded (as in col. 3), the signs and the significance of rate coefficients change dramatically and are no longer consistent with a priori expectations. With this one exception, including or excluding additional explanatory variables for the rate or ceiling has little effect on the estimation results.

The estimated ceiling proportion at the mean of the explanatory variables is 45 percent for column 2. As expected, the proportion of output using the competing technol-

ogy, *MLN*, has a negative effect on the ceiling, and seam width has a positive effect. The ceiling proportion also varies positively with the number of cutting machines. Cutting machines are an older technology, and therefore this variable may be capturing the age of the equipment in the mine instead of the effect of competing technology.

The estimated value for the rate when all the explanatory variables are at their mean levels is .44 for column 2. The signs of the significant variables in column 2 do accord with a priori expectations and also indicate that the structure of the output market does indeed affect the decision to adopt new technology. Captive mines switch to production using continuous mining machines at a faster rate. Higher wages and a higher level of reserves lead to faster adoption, and the rate also increases with time.

Estimating an adjustment model so as to take advantage of panel data and to allow for shifts in the rate of diffusion over time can identify factors that affect the rate of adoption. I conclude that the installed base of earlier competing technologies affects the ceiling or desired proportion of production using the new technology, and through this the adoption of the new technology. The results also highlight the importance of the relationship between investment decisions and vertical integration. In a long-term stable contractual arrangement, such as vertical integration, firms are more likely to adopt firm-specific new technologies.

Diversification by Regulated Monopolies and Incentives for Cost-Reducing R&D

By KAREN PALMER*

Traditional cost-based regulatory methods fail to promote static efficiency in production and do not provide incentives for firms to invest in process innovations that lead to lower production cost in the future. (See Sanford Berg and John Tschirhart, 1988, ch. 10.) Production efficiency may be enhanced if a regulated firm is allowed to exploit economies of scope by diversifying into other unregulated lines of business. If the regulator is able to reduce the regulated revenue requirement due to the cost savings resulting from economies of scope, then some of the benefits of joint production ultimately may be passed on to the consumers of the regulated products in the form of lower prices. Diversification into unregulated markets also increases the firm's incentives to engage in process innovation by providing opportunities for earning profits in unregulated markets. Investments in process innovation can lead to lower future costs of producing the regulated product and potential future price reductions to regulated customers.

I present a model of the firm's decision to diversify into an unregulated market and look at the implications of that decision for a firm's incentive to innovate and for consumer welfare. The firm's choice is strongly influenced by the extent to which the regulator reduces the amount of fixed cost included in the regulated revenue requirement should the firm choose to diversify. I show that if the regulator is able to observe production costs accurately at the time of a rate review, then diversification increases the firm's incentive to innovate and leads

to higher gains in consumers' welfare over time.

I. The Model

I use a three-period model to compare the profit-maximizing behavior of an undiversified regulated firm and a diversified regulated firm. It is assumed that the demand functions for both the regulated and unregulated products do not change over time. The technology used by the firm exhibits economies of scale in the production of the regulated product and economies of scope in the joint production of the two products. The firm is regulated under zero-profit regulation with a one-period regulatory lag; regulators do not adjust prices in response to changes in production costs until the subsequent period. The firm decides whether or not to diversify and how much to invest in R&D in period 1. The full cost reductions from the R&D investment occur in period 2, continue through period 3 and are known with certainty to the firm, but not to the regulator, at the time of the R&D investment. The regulated price is set equal to average production cost (not including R&D expenditures) in the regulated market in period 1 and remains the same through period 2. Price is adjusted in period 3 to yield zero profit on sales of the regulated product. Also assume that the regulator can observe at each rate review all the cost information necessary to set a price that yields zero profit and that the regulatory constraint is binding during the period when a rate review occurs.

If the regulated firm decides not to diversify in period 1, then the present discounted value of its profits over the next 3 periods is

$$(1) \quad \underset{B}{\text{Max}} -B + \delta [\text{Rev}(x_2^u) - \gamma(B) \times [F + C(x_2^u)]] + 0$$

*Fellow, Resources for the Future, 1616 P St. NW, Washington, D.C. 20036. I thank Mike Toman, Dallas Burtraw, Molly Macauley, Steve Polasky, and Tim Brennan for helpful comments on an earlier version of this paper.

where δ is the discount factor, $\text{Rev}(x_2^u)$ is the revenue from selling x in period 2, B is the level of investment in process innovation, and $\gamma(B)[F + C(x)]$ is the cost function for x .

The cost function for x has a fixed component, F , and a variable component $C(x)$ with $C_x > 0$ and $C_{xx} < 0$. Investment in R&D in period 1 reduces both components of cost in subsequent periods through the innovation factor $\gamma(B)$ where $\gamma_B < 0$ and $\gamma_{BB} > 0$.¹ In period 1, $\gamma(B)$ equals one. Only by investing in process innovation can the firm earn positive profits in period 2.

If the firm seeks to diversify into the production of the unregulated product y in period 1, it must obtain the approval of the regulator who may simultaneously lower the regulated revenue requirement and the regulated price in this period. The regulator does this by shifting responsibility for some portion, θ between 0 and 1, of the fixed cost of producing x to the unregulated market. The value of θ is independent of the amount of y produced and remains constant throughout the three periods at the level set by the regulator in period 1. The value of θ designated by the regulator reflects his attitudes about how the benefits of economies of scope should be split between the regulated and unregulated markets. (The regulator could specify different values of θ for different lines of business that the firm might choose to enter.) The higher the value of θ , the lower the portion of joint cost that is included in the regulated revenue requirement and, *ceteris paribus*, the more the consumers of the regulated product benefit from scope economies.²

Prior to making its decision about diversification, the firm learns the value of θ set by the regulator. If the firm decides to diversify and θ exceeds zero, the price of the regulated product is reduced in period 1. The profit-maximization problem for the diversified firm is³

$$(2) \quad \text{Max}_B P_y y_1 - \theta F - C(y_1) - B \\ + \delta [\text{Rev}(x_2^d) + P_y y_2 - \gamma(B) \times [F + C(x_2^d)] \\ - C(y_2)] + \delta^2 [P_y y_3 - C(y_3) - \theta \gamma(B) F]$$

where $C(y)$ is the incremental cost of producing product y in addition to product x .

It is assumed that the unregulated market is perfectly competitive with a price of P_y , therefore, the firm sells the same quantity of y , that which equates price to marginal cost, in each time period.

II. Investment in R&D

According to my model, the profit-maximizing level of R&D expenditures for the undiversified firm falls below the socially optimal level (given x_1) because the firm does not retain the higher profits associated with lower third-period costs. The diversified firm also selects a suboptimal level of investment in B ; however, it selects a higher level of B than the undiversified firm if θ is greater than zero. (Derivations of these and all further results are found in my 1990 paper.)

¹In my specification of the model, I implicitly assume that there are economies of scope between production of x and R&D to reduce the cost of producing x , when having this R&D performed by the regulated firm's suppliers is not considered. This assumption is justified if familiarity with day-to-day operations in the production of x affect the parameters of the γ function.

²Given the technology and the regulatory rules that I specify and the assumed ability of the regulator to attribute costs accurately to either a common cost category or to one of the two products, reducing the regulated product's share of common costs (increasing θ) will lower regulated price and increase output. Us-

ing an Averch-Johnson model of the regulated firm, Michael Crew and Keith Crocker (1990) find that if the regulatory constraint is binding after diversification, more of the regulated product is produced after diversification only if all production costs including those for the unregulated product are included in the revenue requirement.

³I am implicitly assuming that the firm does not engage in any wasteful spending given the chosen technology. Ronald Braeutigam and John Panzar (1989) show that if the regulator knows the breakdown of production costs between joint and attributable costs, then the firm has no incentive to make wasteful expenditures in any cost category.

Three factors contribute to the diversified firm's enhanced incentive to undertake R&D: 1) the one-period regulatory lag; 2) the initial increase in demand for the regulated product in periods 1 and 2 spurred by the reduction in the regulated revenue requirement; and 3) the opportunity to keep some of the gains from R&D in the form of higher profits in the unregulated market in period 3. The last two factors both require that θ be greater than zero. Just as increasing the length of the regulatory lag increases a firm's incentive to invest in R&D (Elizabeth Bailey, 1974), increasing the value of θ also increases the firm's preferred level of B . As θ rises, first- and second-period output of the regulated product increase and the share of the reduction in common costs that is lost to consumers in the form of a lower third-period price falls, both serving to increase investment in R&D.

The firm's decision to diversify or not depends on the value of θ set by the regulator. If θ equals zero, the firm chooses to diversify since the difference between diversified and undiversified profits is positive. However, as the value of θ increases, the profit gains from diversification fall. I designate as θ^* the value of θ at which diversified profit equals undiversified profit. The value of θ^* varies positively with the degree of economies of scope between x and y .⁴ If the value of θ set by the regulator exceeds θ^* , the firm chooses not to diversify and the attending higher gains in production efficiency do not occur.

III. Welfare Effects

A welfare analysis of this increased innovative activity with diversification suggests

that there may be, previously unrecognized dynamic gains in consumers' surplus when regulated firms diversify into unregulated industries. If the cross elasticity of demand between x and y is zero and the firm continues to charge the competitive price for y after diversification and innovation, then consumers' surplus in the market for y is unchanged. In the market for x , consumers' surplus increases in period 3 in the undiversified case as price is lowered to reflect cost reductions due to R&D investments made in period 1. If the firm diversifies and θ exceeds zero, consumers' surplus in the regulated market is higher in periods 1 and 2 due to the initial price reduction. The price of the regulated product falls again in period 3 at the time of the rate review. In each of the three periods, consumers' surplus under diversification exceeds the level attained when the firm remains undiversified because the average revenue requirement is lower in all three periods under diversification.

IV. Diversification and Specialized R&D

While diversification of regulated firms may provide an incentive for potentially welfare-improving innovations, diversification also opens the door for various forms of cross subsidy and other inefficient behaviors on the part of the regulated firm. The opportunities to profit from inefficient behavior increase as the quality of the regulator's information decreases (Timothy Brennan, 1990). However, even a regulator like the one in this model, who is able to monitor and categorize production costs perfectly, is not immune to inefficient technology choice on the part of the firm.⁵ Our regulator also is unable to prevent inefficient allocation of R&D expenditures be-

⁴While scope economies do provide a legal or political justification for regulators to disallow some portion of fixed costs, economies of scope are not necessary for the regulatory policy of disallowing fixed costs to lead to increases in R&D investment. However, *ceteris paribus*, the greater the scope economies between the existing regulated product and any unregulated product, the more attractive is that unregulated product as an additional line of business to the regulated firm.

⁵See Kenneth Baseman (1981), Brennan, and Braeutigam-Panzar. I do not address this problem of inefficient initial technology choice in the model and the regulatory policy is not designed to alleviate this problem specifically. However, if the regulator sets a high value of θ , the firm's incentive to shift to a high fixed-cost technology in order to lower marginal cost in unregulated markets is reduced considerably.

tween the reduction of joint and attributable costs.

To analyze the implications of differentiated R&D investments for the earlier results, I modify the model of R&D investment decisions to allow the firm to disaggregate its innovative effort between reducing common costs and reducing attributable costs as found in Braeutigam and Panzar. I use this model to compare R&D investment of diversified and undiversified firms and the associated reductions in the regulated price across all three time periods. I find that the diversified firm invests more than the undiversified firm both in R&D to reduce cost attributable to x and in joint-cost-reducing R&D. However, the diversified firm is biased vis-à-vis the undiversified firm toward joint-cost-reducing R&D and this bias reduces the magnitude of economies of scope over time. Despite this additional distortion in innovative effort, consumers' surplus is higher in all three periods when the regulated firm diversifies.

V. Conclusions

I have derived a model in which the regulator can induce the diversified firm to invest in R&D by making a reduction in the portion of fixed costs included in the regulated revenue requirement a precondition for allowing the firm to diversify. Under this rule the firm diversifies if the designated value of the fixed cost sharing parameter, θ , is below the firm's breakeven level, θ^* . The diversified firm picks a higher level of R&D investment and consumers of the regulated product are better off if the regulated firm diversifies because of the lower average revenue requirement. The policy of sharing fixed costs leads to higher consumers' welfare gains over time, even if the diversified firm's R&D investment is biased toward fixed-cost-reducing R&D.

The assumptions underlying this analysis are that the regulator is able to distinguish joint costs and attributable costs and to assess accurately *ex post* the effects of R&D investment on the firm's cost function. If the regulator is unable to categorize costs or to observe these cost reductions, then the

negative effects of cross subsidy or distorted technology choice or both may outweigh any long-run benefits to consumers from reduced costs. Two other important assumptions in this analysis are that the market for the unregulated product y is perfectly competitive and that the demand functions for x and y are independent. Violation of either assumption could increase the firm's incentives to cross subsidize and result in lower or negative net gains in consumers' welfare from increased innovation.

Diversification into an unregulated line of business could also increase the number of and the usefulness of new products and services that might be developed by the diversified regulated producer, potentially increasing the level of consumers' welfare over time. For example, allowing a regulated service producer to manufacture the capital equipment used to produce the service could bring a more extensive knowledge of the marketplace for the existing and for potential new services to the R&D process for the equipment manufacturer.⁶ Further research is required to explore these and other possible links between diversification and improved research performance by regulated firms before making significant changes to regulatory policies and curtailing line-of-business restrictions.

⁶Alfred Kahn (1990) uses this argument to justify allowing the regional Bell Operating Companies to manufacture communications equipment.

DIFFUSION OF DEVELOPMENT[†]

Diffusion of Development: Post-World War II Convergence Among Advanced Industrial Nations

By RICHARD R. NELSON*

Over the past half-dozen years, a significant literature has grown up on the phenomenon of "convergence," the erosion of the striking U.S. lead in productivity, incomes, and technology across a wide front, that clearly existed during the quarter-century after World War II. It was Moses Abramovitz' masterly article (1986) that (arguably) started the recent flow of research and writing, and his is (arguably) still the most sophisticated statement of the phenomenon, and articulation of a broad theory to explain it.

Abramovitz posited that the presence of a nation (or a firm?) employing significantly superior technology provides others with a target to emulate, an opportunity for rapid growth, and a context where one might expect convergence. However, he also observed that, even in the post-1960s, not all nations were "converging," and employed the term "social capabilities" to designate the requirements to take advantage of the opportunity. He mentioned an effective education system and appropriate institutional structures, among other things, as components of "capabilities." Abramovitz also noted that there seemed to be something special about the post-World War II period, or the interwar period, or both, because the U.S. lead in productivity and income dated from before World War I, and yet there is little evidence of convergence until the 1960's, even among nations that, presumably, had ample capabilities, in the sense of

an educated work force, modern financial institutions, etc.

I presume that the other two papers in this session will deal with the mixed experience of the countries that were underdeveloped in 1950, and the generally bad experience of the socialist economics which, as it turned out, led to the abandonment of that kind of economic system.

I. How Did the United States Get its Lead?¹

This paper is about the convergence that has occurred among the major industrialized nations. For the most part, the convergence literature takes the U.S. lead after World War II as "given," and pays no attention to exactly what that lead was, and where it came from. My proposal here is that understanding of the sources of the U.S. lead enables one to understand better why there was failure of convergence among the advanced industrial nations prior to World War II, why convergence has occurred so rapidly since 1960, but among only a limited set of countries. My basic argument is that there were two distinguishable components of postwar U.S. technological dominance. One was the lead in mass production industries, and this was of long standing. The other was in "high-tech" and this was new. Each stemmed from different sources. And they eroded for conceptually separate, if institutionally connected, reasons.

While Great Britain was the pioneer and dominant technological power of the first

[†]*Discussants:* Paul David, Stanford University; Donald Harris, Stanford University; Henry Rosovsky, Harvard University.

*Columbia University, New York, NY 10027.

¹The basic argument developed here is presented in more detail in my 1990 article. Gavin Wright (1990) has developed an analysis of the "early" U.S. lead that is strongly complementary to mine.

Industrial Revolution, in a variety of areas the Americans caught on quickly. A number of economic and technological historians have documented the early rise of mechanized production of fire arms in the United States, and the subsequent spread of this technology to other industries.

During the last half of the nineteenth century, a rapidly growing mass market of relatively well-to-do households, and an expanding rail and communication network that broke down distance barriers, led in a number of industries to the rise of large companies engaged in mass production and nationwide marketing. The story has been well described and documented in Alfred Chandler's work. (See particularly his 1977 study) In many of these industries, American firms developed a clear lead in process technology or product design, or both, over British and continental firms. The U.S. firms dominated world production and trade in such diverse products as sewing machines, typewriters, matches, and refrigerated meat, for example. By the 1890's, the United States led the world in steel production, and American firms were widely recognized as the most efficient steel producers.

There were several factors that were special about the American scene that led to these developments. First, by the late nineteenth century, the United States had become the world's largest richest common market. In a context where exportation was not easy, American firms were in a much better position to exploit latent economies of scale than were European firms. Second, large-scale production tended to be capital intensive. High American wage rates, and relative scarcity of skilled labor, encouraged and supported such capital-intensive production. Third, reflecting America's resource abundance, the new technologies tended to be natural-resource-intensive, both directly and indirectly, in that American machinery was low priced relative to machinery produced in Europe, because American metals were cheaper.²

²The advantages lent to American industry by cheap natural resources have been stressed by Wright, and much earlier by Nathan Rosenberg (1976).

Economists looking at this situation through the lens provided by standard price theory would be inclined to propose that market conditions induced American firms to produce in a different manner than the European ones. This does not imply that Americans had command over technology that the European could not have used had conditions there been different. However, in fact, effective command of the technologies in question involved significant elements of learning by doing and using on the part of engineers, mechanics, craftspersons, and managers. Adoption of these technologies by European firms, had they wanted to do so, would have been a very costly and time-consuming business.

The American lead in mass production industries was preserved over the interwar period in large part because economic conditions in the United States continued to warrant larger-scale and more capital-intensive production than in Europe. Barriers to intercountry trade were high during this era. The American market was significantly larger than the market faced by national European firms. American real wage rates were higher, and more capital-intensive production therefore warranted.

In the early years after World War II, Americans continued to be dominant in these large-scale and capital-intensive industries. European engineers and managers clearly recognized American superiority, and that it was of long standing.

I have been arguing that the American post-World War II mass production industries had been around for a long time. In contrast, the American postwar lead in the new high-tech industries of the postwar era (jet aircraft, semiconductors, computers, telecommunications, pharmaceuticals) was a new phenomenon.

By the late nineteenth century, technological advance in the chemical and electrical industries began to take place in industrial laboratories dedicated to invention, and staffed by university-trained scientists and engineers. It was German firms, not British or American, that took the lead in the new industries associated with organic chemistry. In the new electrical equipment indus-

tries, American firms were in the forefront of some fields, but in most had no significant lead over German or British firms, and, in a number of areas, European firms were ahead.

On the eve of World War II, the major American chemical companies had more or less caught up with the Germans, and the major American electrical equipment companies were world class, and doing well in rapidly growing fields connected with radio and electronics. American universities were quite respectable in a variety of the sciences. But there is no evidence of American leadership in these high-tech fields that was on a par with American leadership in mass-production technologies.

However, it is apparent the Americans did take the leadership in the above-named fields after World War II. The Europeans recognized this, and worried about it. What lay behind this new American lead?

The answer, I would argue, lies in massive investments in research and development (R&D) that American firms, universities, and the American government began to make after the war. By the early 1960's, R&D as a fraction of GNP was roughly double in the United States what it was in Europe. This vast investment in R&D was supported and made possible by significant increases in the fraction of young Americans going on to higher education and into science and engineering.

A small but important fraction of this greatly expanded pool of scientific and engineering talent was employed in the U.S. university research system. Support for this massive increase in university research was largely provided through the government.

However, the lion's share of the increased investment in R&D occurred in American industry. Part of the increase in corporate R&D was the result of major increases in private R&D funding, based on optimistic beliefs about the profitability of such investments which, by and large, turned out to be well-founded. Part was due to massive DOD and, later, NASA investments in the system. As it turned out, Department of Defense R&D expenditure and procurement was an extremely important factor behind the rise

of U.S. industrial predominance in commercial jet aircrafts, semiconductors, and computers.³

While commentators at the time treated "spillover" from military R&D as if it were a natural kind of event, I propose here that the circumstances in the 1950's and 1960's were somewhat unusual. It turned out that the kinds of weapons the armed services wanted then involved technologies that soon had major civilian use. During the nineteenth century, army demands for guns with interchangeable parts put in place a machine-tool technology that later had widespread civilian use. However, it is arguable that, in the normal course of events, the flow is more from technology developed for civilian purposes to military needs, than the other way around, and when the military goes for a technology not available in the civilian sector, later spillover is quite limited.

By the mid-1960's, the new American lead in high-tech industries, as the old lead in mass production industries, was widely taken as a fact of life, a source of pride for Americans and of concern for Europeans, but presumably a fact not easy to change. Ironically, as we now know, by then, American dominance was fast eroding. It was shrinking both in the areas of longstanding American preeminence (mass-production industries) and in the new high-tech fields that the United States seized after the second World War.

II. Convergence

I propose that this account of the nature and origin of the U.S. post-World War II lead, or rather the twin leads, helps one to understand the subsequent convergence phenomenon and its timing. It suggests that not just one, but several, different things were going on behind the scenes.

One central thing was the opening of world trade in manufactured goods, and in

³See the chapters by David Mowery and Nathan Rosenberg, Richard Levin, and Barbara Katz and Almarin Phillips, in my book (1982).

raw materials. With that, the world became "a common market," and the American advantage in scale-and resource-intensive production, that it had had for almost a century, eroded. With national boundaries no longer such an obstacle, it made sense for European industrialists to rebuild their production capacity along American lines. That they did, and as their productivity and efficiency jumped, European and Japanese firms became competitive. Their sharply rising exports both reflect this, and were a precondition for successful adoption of scale-intensive technologies in the first place. And real wages rose with productivity thus justifying and supporting higher capital intensity.

The erosion of American dominance in high-tech industries is also a story of opening trade diminishing early American scale advantages, and involves other elements. Up until the mid-1960's, the American military market for semi-conductors, and computers, that was basically reserved for American firms, counted for a large share of total demand. By the mid-1960's, however, the civilian market for these products had outstripped the military in scale, and this market was open to foreign competition.

At the same time, technological communities were becoming increasingly transnational. Partly this was part and parcel of the internationalization of business that was occurring. Partly it was the result of the greater ease of communication and travel that marked the period. As a result, the general elements of technological knowledge became widely accessible to trained scientists and engineers, whatever their nationality.

However, development of operational capabilities in the high-tech industries required massive investments—in R&D and the training of scientists and engineers needed to do R&D, as well as in plant and equipment. By the late 1960's, the major European nations and Japan were making these investments. Scientists and engineers as a fraction of the work force, and R&D as a fraction of GNP, rose to approach American levels.

At the same time, a considerable amount of scattered evidence suggests strongly that the large American military R&D efforts, that I have argued was a plus in the 1950's and early 1960's, began to be a minus or, at least, not a help. The rise of civilian demand for semiconductors and computers, and for commercial jet aircraft, stimulated very large-scale privately financed R&D efforts to meet these demands. At the same time, military R&D increasingly was being focused on special attributes particularly valued by the military. By the 1970's, it is arguable that there was much more "spillover" from civilian R&D to the military, than the other way. Yet the United States continued to spend proportionally far more of its R&D on military projects than did the other industrial nations. By the 1980's, Germany, Japan, and several other nations were spending a larger fraction of their GNP on civilian R&D than was the United States.

Let me summarize. The U.S. technological lead after World War II had two different components: an old part in mass-production industries stemming from the fact that for over a half-century, the United States was the world's largest common market; and a new part in high-tech stemming from massive investments in R&D and training of scientists and engineers. The twin leads eroded as the world became a common market, and nations with the requisite "social capabilities" moved to catch up, and as those same nations invested in the special social capabilities needed to compete in high-tech R&D and higher education.

This is a much more elaborate and complex explanation of the convergence phenomenon than that contained in many of the recent writings concerned with it. Several of these portray convergence as something that is more or less automatic, and thus cannot come to grips with why convergence was so much more rapid in post-World War II than before, and why there are only a few members of the convergence club. In my view, Abramovitz' treatment of the matter, which stresses social capabilities, and, also, hindrances to European industry dur-

ing the interwar period, remains the most sophisticated and illuminating general discussion of the matter. I consider my treatment here an elaboration and extension of his.

Diffusion of Development: The Soviet Union

By MARSHALL I. GOLDMAN*

Younger economists often find it difficult to believe that, at one time, the Soviet approach to economic development, or at least the sanitized version of it, was often held out as a worthy model for developing countries. Even by most alternative calculations of Soviet economic growth, the Soviet Union seemed to be making great strides. The Soviet Union showed that they had mastered advanced technology by being the first to send a man into space, while on the ground they reported record harvests and some of the world's fastest growth rates in steel production and in the output of other basic raw materials. The Soviets seemed to have transformed Western development techniques—highlighting some aspects and abandoning others. Until the mid-1960's at least, the Soviet Union seemed to have mastered the secret of economic development and there seemed to be some basis to Nikita Khrushchev's claim that, by 1970 or 1980, the Soviet Union would be able to overtake the United States and move on to the attainment of full communism.

If the Soviet economy was doing so well, why is it that suddenly it seems to be collapsing? Nor is it just a simple slowdown. Many Soviet economic institutions have simply disintegrated. What is happening now resembles the breakdown in some Third World countries, or parts of Europe and the United States in the early 1930's. There is no simple explanation for what has happened. But, in part, some of the Soviet Union's current problems are a consequence of the approach it took to development in the 1920's and 1930's. For a time, Soviet leaders assumed that they could suspend or ignore many of the governing laws of economics, keeping what suited them and

rejecting what did not. They are now discovering that it is dangerous to mess with macro- and microeconomics.

I

Stalin was determined to accelerate his country's economic growth. He was worried about a potential military threat from Germany, and he realized that he had few friends and even fewer prospects for revolution in the capitalist world. Thus he concluded that he had to move fast and, as a consequence, he decided he could not rely on traditional and time-consuming economic methods to jolt his essentially agrarian society into an advanced industrial powerhouse.

Without spelling out exactly what it was that he was doing (he probably was not fully aware of the theoretical consequences of what he was doing since they were much less fully understood at the time), in effect, Stalin declared macroeconomics null and void. There would still be taxes, government expenditures, borrowed money, and interest rates, but there was no thought that these procedures would be used to fine-tune the economy, or to increase or decrease the size of the multiplier. At most, these were necessary mechanisms for the running and financing of the government and specific industries.

Microeconomics was set aside in much the same way. In a sharp departure from other economies at the time, Stalin decreed the nationalization and collectivization of all the means of production. All factories, shops, and farms became state entities. As such, state authorities assumed the right to issue orders about the most elementary activities. Even the decision to import or export, as well as control over foreign currency, became a monopoly of the Ministry of Foreign Trade.

Since they owned and determined the behavior of almost all the country's means

*The Kathryn W. Davis Professor of Soviet Economics at Wellesley College and Associate Director, Russian Research Center, Harvard University, Cambridge, MA 021138.

of production, finding a better equilibrium of supply and demand was not something Soviet leaders worried about. Besides, most of those put in charge of the economy were engineers who concerned themselves more with increasing production, especially of heavy industrial products. To bring about the accelerated growth that Stalin wanted, the country's engineers and planners came up with the idea of the yearly and 5-year plans. Shortages were essentially treated as short-term phenomena, that sooner or later were sure to be eliminated through improved planning procedures and accelerated plans. There was seldom any concern that, at existing prices, there were too many customers and not enough supplies. These temporary glitches would ultimately disappear and production would increase. That was the main priority, and increases in production became the measure for judging factory manager as well as national economic performance. In effect, an administered system was put in place in which planners, administrators, Gosplan, Gossnab, and the various industrial ministers, including the Ministry of Foreign Trade, set industrial output targets and allocated supplies of capital and labor. This superseded what in other societies was determined by individual decision makers guided only indirectly by the government's monetary and fiscal policies.

Inevitably, the Soviet system gave rise to enormous disproportions, some of which had serious consequences. The full measure of what was happening, however, was masked by the unrestrained use of the country's abundant stock of raw materials and labor. This practice was institutionalized by the deliberate decision to set low prices on raw materials. The low raw material prices were combined with an incentive system called "val." The val system rewarded managers for increasing the gross ruble value of their output compared to what had been reported the year before. Since gross ruble output was measured simply by adding up the costs of inputs, managers were in effect induced to use as many inputs as possible. As a result, Soviet manufactured products became heavy, and energy and raw material became wasteful. This was exemplified in the way the Soviet Union built airplanes.

They were heavy and required extra powerful engines. This made Soviet planes unsalable in the capitalist world because commercial airlines were unwilling to pay the extra money needed to fuel those engines.

None of this was particularly disturbing to Soviet authorities. There were, after all, abundant reserves of raw materials that could be tapped by simply assigning more of the Soviet Union's abundant labor reserves to Siberia. Even some American economists supported such a utilization of resources. Given what at the time seemed to be the Soviet Union's abundant oil reserves, there seemed to be nothing wrong with the Soviet Union increasing its exports of petroleum in order to pay for increased imports of grain. (See Ed Hewitt, 1983; John Vanous, 1982.)

The only flaw in this reasoning is that Soviet energy supplies are limited and as more readily accessible supplies are used up, it becomes more and more costly, even by Soviet standards, to find additional reserves. Moreover, quantity of output increasingly became a less important criteria for determining economic success. With the growth of high technology and miniaturization, it was quality that counted. It was time to call off the race to build the world's largest microchip.

II

The Soviet administrative planning system was ill-suited to deal with the shift in emphasis from quantity to quality. Procedures designed to take advantage of the Soviet strengths under the old system seemed more and more inappropriate, if not counterproductive. This is well-illustrated by a look at what happened when the Soviet Union began to pay more attention to foreign trade.

Under the old regime, foreign trade was the monopoly of the Ministry of Foreign Trade and its foreign trade organizations (FTOs). This, it was thought, would give the Soviet Union an economic advantage in dealing with the anarchy of the marketplace. As a solitary buyer for the whole country, the Ministry of Foreign Trade was able to play off one contending capitalist seller against another in order to obtain the

lowest price possible. This ability to manipulate made possible the "great grain robbery" of 1972.

The monopoly also fit in well with the Soviet Union's political concerns. For example, for security reasons, Soviet authorities insisted that contact between Soviet and foreign trading partners be strictly controlled. In the vast majority of instances, that meant that foreign buyers and sellers usually had no contact with their Soviet suppliers or buyers. All transactions were transmitted through the filter of the FTO. This precluded feedback or after-sale service.

In foreign trade, as elsewhere in the economy, the impact of macro- and micro-economic considerations was severely circumscribed. While Soviet officials did seek to insure some level of equilibrium between hard currency imports and exports, they did not let the market determine access to hard currency reserves. Exporters, particularly the ministries of oil and gas, the source of 60–70 percent of the Soviet Union's hard currency earnings, received almost none of the proceeds. Hard currency or *valuta* was instead allocated on an arbitrary basis. Political considerations seemed to be as important as economic criteria. For example, the chemical industry, whose Minister Leonid Kostandov seemed particularly well connected, was consistently allocated 25 percent of the hard currency set aside for machinery imports, even though the chemical industry accounted for only 8 percent of the Soviet Union's total industrial investment. (See Philip Hanson, 1981.)

Since there was no need to repay that hard currency (which was fortunate since the earnings from the anticipated surge in petrochemical exports never seemed to materialize), then *valuta* was in effect a free good. Thus no one had to worry about the suitability of scale or payback periods, or feasibility studies. This contributed to gigantomania or the large-typewriter-carriage syndrome. Political clout in an office was easily measured by the size of its typewriter carriage. Important offices had big carriages—unimportant offices had small carriages. It was immaterial whether or not those ex-

tra large carriages were ever used—some day they might be and that was enough. Machinery specifications were determined in the same way.

Politics even played a role in plant location. Factory locations would occasionally be determined by the need to repay a favor to a local official, rather than to access to the necessary raw materials. Based on some interviews with Western exporters, I was told that an American-built milk plant, for example, was located in an area where there was a shortage of cows. European and American chemical company executives reported that they were told to install a petro-chemical plant in Tomsk and Omsk, even though the needed raw materials were not readily available in those regions.

Political considerations also accounted for the persistent refusal of ministries to cooperate with one another. They gave preference, instead, to units within their vertical jurisdiction. Thus according to Western exporters, individual ministries normally refused to share information with one another about Western imports, and similarly refused to join together to set up such things as a parts center or a wholesale operation. In the administrative planned system, that might actually complicate rather than simplify operations.

Unlike South Korea, where there was also government intervention and where prices were also insulated from some market forces, Soviet managers were not made to compete in world markets. Thus there was no reason to seek to enhance product quality or competitiveness. In effect, Soviet managers were sheltered from the competitive rigors of foreign trade, that could have served as a stimulative force in the same way as Janos Kornai's hard budget constraints.

III

By the time Mikhail Gorbachev became General Secretary of the Communist Party, there was fairly widespread agreement that the existing system had not helped the Soviet Union compete with the West. It was not just that the quality gap seemed to be

growing, the Soviet Union also seemed to be falling behind quantitatively. Thus Gorbachev set out to reduce, if not abolish, many of the features of the centrally planned system. Ministries were abolished and reorganized, and ministries and chairmen of Gosplan were continuously replaced in an effort to find someone who could remedy the Soviet Union's problems.

Unfortunately for Gorbachev, he succeeded in destroying portions of the old order before he could replace their functions with processes operating under the new order. As a result, he found himself having to deal with some of the worst aspects of both communism and capitalism. He began to unleash macro and micro forces before he could put in place the restraints that evolved in capitalism to temper their impact.

The best illustration is the macro consequence of inflation. It turns out that the Soviet Union had incurred an annual budget deficit for at least a decade before Gorbachev came to power. But, like a low-grade infection, it was not considered to be anything worth worrying about, particularly in an environment where macroeconomics was considered to be nonoperational. Thus Gorbachev paid little heed to the effect of increasing expenditures on machine tools and decreasing revenues because of the curb on the sale of vodka. The 18 billion ruble budget deficit in 1985, Gorbachev's first year, differed little from the deficits of preceding years. In 1986, however, there was almost a threefold increase in the deficit, and the problem was no longer trivial. By 1989, the deficit exceeded 100 billion rubles, equivalent to about 10 percent of the Soviet Union's GNP. By 1990, no one seemed to know how big the deficit was any longer. By some estimates, it may have reached 200 billion rubles.

Belatedly, Gorbachev came to appreciate the significance of what had happened, but by then it was too late. In his own words, he acknowledged that in October 1990, "we lost control over the financial situation in the country. That was our most serious mistake in the three years of perestroika." And 5 years too late, he went on to note,

"achieving a balanced budget today is the number one task and the most important one" (both citations found in *The New York Times*, October 20, 1990).

The reason for Gorbachev's concern was that, by 1987, the deficits that were financed in large part by the issuance of money, gave rise to an increasingly large inflation. Again, no precise figures are available but, by 1989, some estimates indicated that inflation was at the level of 20 percent a year, and that there was a growing fear of hyperinflation. Inflation, in turn, led to hoarding as consumers tried to protect themselves from the fall in the value of the ruble. The result was a collapse of the distribution system. As Vasily Selyunin, an acute economic observer, put it, "during the second half of last year [1989], trade began to fall to pieces before our eyes" (*Sotsialisticheskaia industriia*, April 6, 1989).

The irony is that just when the Soviet Union seemed ready to open the institutional doors to market processes, the Soviet Union found that it first must pay its bills for all those years of denying the central role of economics. The Soviet Union today has to deal with inflation, shortages, and economic separatism. The decision to end the monopoly of the Ministry of Foreign Trade by abolishing the Ministry has caused similar problems. The expectation was that with no monopoly control, foreign trade might some day become more responsive to Soviet consumer wants. In the meantime, however, that lack of central control has resulted in a record trade deficit, and, by 1989, the Soviet Union found it could not pay the bills owed to foreign suppliers.

It was not only the economic, but the political, bills of the past that have begun to frustrate Gorbachev's reform efforts. After several months of indecision and policy reversals, Gorbachev finally decided to encourage the formation of private and cooperative businesses and family farms. The move to private business was slow at first, but ultimately attracted some venturesome entrepreneurs. But the indecision and continuing controls on such activity serves to prevent an increase in supply large enough to bring down prices. The expansion of the

supplies of flowers in Soviet cities proves that such an increase is possible, but more typical is the reluctance of the peasants, especially in the Slavic parts of the country, to pick up Gorbachev's offer to set up their own family farms. Remembering what happened to the kulaks in the 1930s, as well as how Khrushchev simply reduced the size of their plots and the number of their cows in 1960, the peasants decided that the higher return that they might obtain from an investment in land and livestock was not worth the risk that they would lose it all after another shift in the political pendulum. Thus, as of July 1, 1990, after almost 3 years of trying, there were only 30,000 family and private farms in the entire Soviet Union. Over one-half of these farms were in the republic of Georgia and one-third were located in Latvia, Lithuania, and Estonia. Meanwhile there were only 900 of these farms in the Russian Republic and a mere 12 farms in the Ukraine (*Ekonomika i zhizn'*; November 1990).

To an economist, the effect of all these upheavals is that the time horizon of the average Soviet citizen has been cut back sharply. Few are willing to invest in the future, which of course makes it all the more difficult to cope with the present. The minute any one in the Soviet Union smells money, especially foreign *valuta*, they make a grab for it. Thus even joint ventures like Combustion Engineering and McDonalds have fallen victim to this pressure. Instead of taking such efforts and turning them into showcases, that would presumably attract similar investments from outside the Soviet Union, the Soviets instead milk them immediately. Thus, in November 1987, Combustion Engineering invested \$8 million in a joint venture called Applied Engineering Systems. This led to an immediate increase in the yield of some Soviet oil refineries and profits in dollars for the American partner. However, after a while, the Soviet partner began to disregard the need for financial controls. Fancy cars became more important than basic engineering, and, by November 1990, the American partner found it necessary to withdraw its staff from the Soviet Union.

McDonalds encountered similar problems. Rather than wait for profits to accrue from a profitable operation, the Soviet partner decided instead to take its money out at the front end of the operation. In less than 10 months time, the Soviet partners (the Moscow City Council), decided instead to raise the joint venture's office rent tenfold and the price of the meat that the joint venture used by sixfold. Since McDonalds was not selling for dollars, that meant that the local authorities were not even prepared to wait for *valuta* to be earned. McDonalds in turn found it necessary to double prices simply to pay its ruble bills. In the meantime, its Moscow partner was able to raise the yield far above that needed to stay ahead of inflation. The message for the hesitant investors from the West is hesitate some more.

IV

Because of distortions and distrust brought on by Stalinist central planning, the belated adoption of traditional economic market stimuli had a perverted rather than a positive impact. Instead of facilitating healthy economic growth and constructive responses, the tendency has been to put a premium on instantaneous profit maximization. Like the corn hog cycle cobweb that explodes rather than converges, the diffusion of normal economic processes in a severely repressed society like the Soviet Union works to exaggerate rather than dampen economic distortions.

He is usually quoted in conjunction with political change, but Alexis de Tocqueville's comments that "the perilous moment for a bad government is when that government tries to mend its ways," seems to be just as apt when the government decides to acknowledge the reality of macro- and micro-economics.

Diffusion of Development: The Late-Industrializing Model and Greater East Asia

By ALICE H. AMSDEN*

A striking feature of late industrialization is its regional bias. East Asia, both north and south, has encompassed many of the fastest industrializing countries, including Japan, South Korea, Taiwan, Malaysia, Indonesia, and Thailand (Singapore and Hong Kong, although prospering, are distinct because they never transformed themselves from an agrarian base, the usual meaning of "industrialization"). Between 1960 and 1988, industry grew annually by 10.6 percent in East Asia, but by only 6.3 percent in all developing regions (World Bank, 1990).

East Asian growth has not been uniform; the Philippine's performance has lagged. But there are no analytical shortcuts to determine why East Asia generally has boomed by contrasting it with the deviant Philippine case. For example, for over a decade the Philippines promoted exports, a policy that is sometimes credited with greater East Asia's success. Between 1973-80 and 1980-86, the Philippine's ratio of manufactured exports to manufactured value-added nearly doubled, but its economy stagnated (as did the export-oriented economy of Puerto Rico) (UN ESCAP, 1990). Thus, the key to understanding East Asia's success must be sought beyond export activity (or education, in which the Philippines and Puerto Rico have excelled as well).

Equitable land distribution, a structural factor general to East Asia but not to the Philippines, probably does go far in explaining divergent intraregional (and interregional) growth rates. East Asia's equitable land distribution by world standards, a virtue in itself, also appears to underlie its equitable distribution of wages and salaries, which has helped keep social conflict and inflation in check, which, in turn, seems to

encourage high savings rates. Nevertheless, the relationship between industrialization and income distribution is more complex than the above comparison would suggest. Brazil, for example, with a highly skewed income distribution, grew exceptionally fast for over 25 years. Growth has also been rapid in East Asian countries whose income distributions are not very equitable—say, Thailand, and Indonesia. In the 1980's (or 1970's in some cases), the income share of the top quintile of the population exceeded that of the bottom quintile by a factor of 4.0 in Japan, 4.3 in Taiwan (Kuo-Ting Li, 1988), 4.9 in South Korea, 7.6 in Singapore, 11.2 in Thailand, 11.9 in Indonesia (rural income, Alan Gelb, 1988), 12.1 in Hong Kong, and 16.1 in the Philippines (the comparable figure for Mexico, Brazil, and the United States was 15.4, 27.7, and 10.7, respectively). (See UN, 1985.)

Evidently no single variable can substitute for a more general theory of late industrialization to explain divergent growth trends. At least two approaches to the formulation of such a theory are possible. One is to apply the "flying geese" approach (originally presented by Akamatsu), according to which transfers of technology, foreign investment, and trade between richer and poorer parts of a region generate development through a restructuring in the division of labor (see M. Shinohara, 1972). Another is to analyze the general model behind late industrialization and then to theorize why only some countries have been able to assimilate it.

Without question, the East Asian region has reaped positive (and some negative) externalities from overseas Chinese entrepreneurs and from Japan, the late-twentieth century's most dynamic economy. Nevertheless, the flying geese metaphor raises more questions than it answers and is no substitute for the second approach. By

*Professor of Economics, New School for Social Research, 65 Fifth Avenue, New York, NY 10003.

way of illustration, when American industry was "number 1" worldwide in the 1950's and 1960's, the flying geese pattern ought to have obtained in the Western Hemisphere, given large flows of technology, investment, and trade between North and South America. Yet neither has most of South America developed nor is it obvious that whatever development has occurred reflects regional externalities. Regional resource transfers and restructuring have to be placed in a larger analytical context to make sense, particularly in East Asia, all of whose fast-flying geese seem to be guided by a similar radar system.

I. Industrializing Through Learning

There are two potential models to explain late industrialization: an institutional one, as outlined below, and a market-oriented one (with overlap between the two). In the market model, industrialization is a matter of "getting the prices right" and specializing. Low-wage countries are supposed to develop by exporting labor-intensive commodities (ignoring raw materials), and presumably the fastest growing countries are those that most closely follow their comparative advantage. Nevertheless, factor proportions, the pillar of price theory, does not capture the dynamic of industrial change in either the eighteenth or nineteenth centuries. The first industrial revolution in Great Britain was largely driven by a series of technological changes that, for all practical purposes, are exogenously determined in the market model. Come the Second Industrial Revolution a century later, neither Germany nor the United States industrialized by competing against Britain on the basis of low wages. In fact, German and American wages tended to exceed Britain's. Both Germany and the United States out-competed Britain on the basis of a new wave of innovations and another phenomenon that sits uneasily in the market model—economies of scale.

In the twentieth century, the defining characteristic of industrializing "late" is the absence of new technology—even in leading enterprises. Beginning with Japan, late in-

dustrializers have initially not had the competitive asset of pioneering products and processes, which is what differentiates them from earlier industrializers (see my 1989 study). Innovators also borrow technology from their competitors, but late-industrializers are entirely dependent on "learning" in order to compete. This imperative is what gives a common development dynamic to an otherwise diverse set of late-industrializers, say, Malaysia, Mexico, Turkey, and Japan (although in many respects, Japan is unique).

In the market model, the answer to the question of how learners can export or compete against imports without pioneering technology is simple: if they follow their comparative advantage and get the prices right, then they can compete on the basis of low wages. This presumes that lower wages in the least-developed countries can triumph over higher productivity in countries one notch more industrialized. The general assumption is that production functions are everywhere identical so that the most labor-intensive commodities are indisputably the comparative advantage of the lowest-wage producers.

The empirical evidence from East Asia, however, casts doubt on this assumption. For example, a study in the 1930's to ascertain why the Japanese textile industry was bankrupting Lancashire concluded that Japan's lower wages were not responsible (see G. E. Hubbard, 1938). Wages were discounted as the critical variable in the presence of Britain's segmented labor market. Wages of young, female labor in Lancashire were not much higher than in Japan's textile mills. If wages alone mattered, Britain's textile industry might have victored. Instead, Japan's superiority was attributed, among other factors, to its more modern production facilities that, from the perspective of market theory, should have been capital-rich Britain's strong suit.

The superior infrastructure, production equipment, and management of Japanese textile companies in the 1960's made it impossible for Korean and Taiwanese textile companies to compete against them exclusively on the basis of lower wages, even after Korea and Taiwan liberalized their

economies and got the price of their exchange rate right to the point of satisfying the Bretton Woods institutions. Even in a labor-intensive sector like textiles, and even with aid-financed, modern infrastructure, the governments of South Korea and Taiwan *had* to intervene to offset Japan's higher productivity with a wide range of subsidies, far wider than those warranted to support infant *innovators* in the second industrial revolution. Once the exchange rate was devalued, subsidies were used deliberately to get prices "wrong" in order to stimulate investment and trade.

In the market model, the plight of a low-wage country that cannot compete in labor-intensive industries against the higher productivity of a higher-wage country is resolved by introducing either inward direct foreign investment from more technologically advanced countries or further exchange rate devaluations. Yet no foreign investor would invest in a low-wage country if it could make higher profits in a lower-cost, higher-productivity one. Further currency devaluations might reduce real wages and increase competitiveness, but not by much (if at all) if they raised the cost of imported wage goods (or other production inputs).

This dilemma is tautologically dismissed in price theory as a "market failure." In practice, even after devaluing, most countries struggling to industrialize without a new product or process cannot compete on the basis of low wages in a critical mass of industries, a fortiori, when their infrastructure and educational systems are relatively poor. Natural resources and handicrafts may provide a supplementary source of capital accumulation and an alternative engine of growth—as in Malaysia, Indonesia, and Thailand. Yet these countries are exceptionally rich in natural resources, and have still subsidized their non-resource-related industries to foster long-term growth.

II. Subsidy Allocation Principles

East Asia has generally been more successful at industrializing than other learners not because it has bowed deeper at the altar of free markets, but because it has operated

with a different subsidy allocation principle. This has increased productive efficiency so that the "wrong" prices have been right, and fewer subsidies have been needed to create a cost advantage. In slower-growing late-industrializing regions, subsidies have tended to be allocated according to the principle of giveaway, in what has amounted to a free-for-all. In East Asia, beginning with Japan, there has been a greater tendency for subsidies to be dispensed according to the principle of reciprocity, in exchange for concrete performance standards with respect to output, exports, and eventually, R&D.

For example, the government in South Korea disciplined its big business groups by means of price ceilings, controls on capital flight, and incentives that made diversification into new industries contingent on performing well in old ones. Thailand's Board of Investment made subsidized credit and protection from competitive imports dependent on its clients' compliance with sequential performance standards, including exports and local content targets. Taiwan's state-owned bankers have been held personally responsible for loans to business, and have carefully monitored them.

Late industrialization everywhere has involved a high degree of discipline of labor, but what distinguishes East Asia is not just its discipline of labor, but also its discipline of capital. Because a low-wage advantage cannot offset a high-productivity advantage in enough industries to spur development, government intervention is a necessary evil. The more subsidy allocation is disciplined and monitored, the faster growth.

III. Import Substitution cum Export Activity

The counterproposition, that the right market prices are necessary and sufficient to promote industrialization, implies that exporting requires no prior period of subsidization. It is enough that as a country's factor endowments change, it gains new comparative advantages, whereupon exporting can begin at once.

Nevertheless, a large share of East Asia's manufactured exports has involved a lengthy period of subsidization (during which time

incentives seem to have favored domestic sales over exports). Taiwan's and South Korea's textile exports in the 1960's arose on the basis of aid-financed incentives in the 1950's. For 25 years no foreign cars were to be seen on Korean roads and no Korean cars were to be seen on foreign roads. Most of Thailand's and Indonesia's non-resource-related manufactured exports in the mid-1980's began receiving protection in the mid-1960's.

Granted the provision of what has become standard "standby" incentives to exporters regardless of industry, the policy problem is how to insure that after an industry is subsidized for possibly lengthy periods, it achieves world-competitive levels of productivity and quality. Such micro efficiency lies at the heart of East Asia's export success.

The interconnected factors behind East Asia's micro efficiency extend from the shopfloor level to the state. Briefly, in all late-industrializing countries, the strategic focus of the firm tends to be on the shopfloor, because that is where borrowed technology is made to work. East Asia has managed the shopfloor exceptionally well, however, because the wage gap dividing managers and workers is relatively narrow, educational levels are high, performance-based bonuses are a large share of wage payments, etc. In most late-industrializing countries, the widely diversified business group is the predominant form of enterprise, sometimes large in scale (as in Japan and Korea), sometimes small in scale (as in Taiwan and Thailand). For a variety of reasons, however, such enterprises have flourished in East Asia and have diffused "best practice" management techniques to sundry industries. Finally, East Asian micro efficiency has excelled because, as argued above, the subsidy allocation process at the macroeconomic level has been relatively disciplined, and government has been able to prevent the "wrong" prices from being incorrect.

Market forces and the state have divided the labor of disciplining East Asian business. During an industry's import substitution phase, the state has typically been the disciplinarian while during its early export

phase, that role has fallen to the market. Then during an industry's "neo-import substitution phase," when subsidizing R&D and shifting into a higher-quality market segment come on the agenda, the state's dominant role resumes—as became evident by the late 1980's in Taiwan, South Korea, Singapore, and even Hong Kong.

IV. The East Asian Puzzle

An institutional model of late industrialization can be said to be taking shape conceptually. Whereas industrialization in the eighteenth and nineteenth centuries was propelled by new products and processes, late industrialization is being driven by borrowing technology or "learning." In the absence of pioneering technology, low wages even in labor-intensive sectors usually fail to provide a cost advantage at market-determined prices. Persistent problems of competitiveness even after sharp exchange rate devaluations have compelled the state to play a more active role than in the past. The absence of pioneering technology has also meant that business enterprises are less structured around a single technology than previously, and are more solicitous of shopfloor productivity and quality than firms that evolved as innovators, with a strategic focus on design and R&D.

This general model of late industrialization appears to work only under certain conditions, however, and the theoretical task ahead is understanding more about what these conditions are, at both the macro and micro levels. The foregoing discussion focused only on the former, where the East Asian evidence suggested that in subsidy-dependent industrialization, growth will be faster the greater the degree to which the subsidy allocation process is disciplined and tied to performance standards—exports possibly being the most efficient monitoring device. The disciplinarian of business activity has thus shifted over time, from simply a competitive market structure in the first industrial revolution, to Schumpeterian gales of technological change in the second industrial revolution, to an interaction of market forces and state intervention in late industrialization.

After specifying the general model, and stating the conditions under which it is likely to work, the final task is determining why such conditions are present in some countries but not in others. This task is probably the hardest, analogous analytically to pinpointing why particular companies succeed or fail. The puzzle of late industrialization has become identifying those qualities that are intrinsic to East Asia which have enabled its state to discipline business, and its diversified business groups to motivate labor, better than other regions.

Whatever role culture has played in East Asia's development, it cannot simplistically be invoked to explain its states' developmentalism. The exemplary East Asian states after the 1960's were egregious rent seekers in the 1950's—to wit, Chiang Kai-shek in Taiwan and Syngman Rhee in South Korea. The Taiwanese and South Korean states only became developmental pragmatically. Once they began not just to subsidize business but to impose performance standards on it (not least of all export targets), then growth increased. As growth increased, the state became more committed to economic development and allocated more resources to it, which increased development further. Thus, the state transformed the process of

economic development and, in turn, was transformed by it.

THE ECONOMIC IMPACT OF IMMIGRATION[†]

Immigrants in the U.S. Labor Market: 1940–80

By GEORGE J. BORJAS*

Immigration is an increasingly important component of demographic change in the United States. The significant role played by immigration in recent years sparked the development of a large literature analyzing a fundamental aspect of the immigrant experience: How do immigrants perform in the U.S. labor market?¹ A key result in this literature is that the skills of successive immigrant waves declined in the past two or three decades.

This paper continues to explore the extent and causes of the decline in immigrant skills during the postwar period. Prior to 1965, immigration to the United States was guided by the national-origins quota system. This visa allocation system awarded visas to countries based on the representation of the national origin group in the U.S. population as of 1920. The 1965 Amendments abolished the national-origins formula, thus redistributing visas across source countries, and established a system where visas are mainly given to relatives of U.S. citizens or residents.

The empirical analysis shows that a single factor, the changing national origin mix of the immigrant flow, is mainly responsible for the decline in immigrant skills.

I. Data and Descriptive Statistics

The study uses the *Public Use Samples* from four of the five decennial censuses

available since 1940. The 1970 and 1980 Censuses report the calendar year of immigration, while the 1940 and 1960 Censuses report the place of residence 5 years prior to the survey.² These four censuses allow the creation of a “recent immigrant” sample: the group of persons who arrived in the 5-year period prior to the census. Inter-censal comparisons then document the changing skills across successive cohorts. In each census, the analysis is restricted to men aged 25–64 who do not reside in group quarters, who are not self-employed, and who were employed in the civilian sector in the year prior to the census.³ Initially, the recent immigrant sample in each census will be compared with a similarly aged group of natives.

I focus the analysis on three variables: years of completed schooling, the (log) wage rate, and the (log) wage rate adjusted for differences in socioeconomic characteristics between immigrants and natives (including education, age, marital status, and metropolitan residence).⁴ Panel A of Table 1 reports the differences observed between recent immigrants and natives in each of the censuses.

Consider initially the educational attainment of the native and recent immigrant

¹The literature is surveyed in my 1990 book and by Michael Greenwood and John McDowell (1986).

²The 1950 Census does not provide any information on year of immigration (except for place of residence in 1949).

³The 1/100 samples of immigrants and natives contained in the 1940 and 1960 *Public Use Samples* are used in the analysis. The 1970 immigrant extract contains a 2/100 sample, while the 1980 immigrant extract contains the entire 5/100 A File. The 1970 sample of natives is a 1/1000 extract, while the 1980 sample of natives is a 1/2500 extract.

⁴To calculate the adjusted wage differentials, I estimated separate wage regressions for natives and immigrants in each census. The adjusted differential is evaluated at the sample mean of immigrants in each census.

TABLE 1—EDUCATION AND WAGES OF RECENT IMMIGRANT COHORTS IN POSTWAR PERIOD

Differences Between Recent Immigrants and Natives	1940	1960	1970	1980
A. Aged 25–64				
Education	.753	.412	-.222	-.664
Log Wage	-.031 ^a	-.128	-.160	-.299
Adj. Log Wage	-.026 ^a	-.113	-.149	-.224
B. Aged 18–24				
Education	-.231	-.285	-.835	-.313
Log Wage	.521	.331	.249	.215
Adj. Log Wage	.353	.472	.210	.128
C. Aged 25–44				
Education	.326	-.286	-.862	-1.354
Log Wage	.011 ^a	-.126	-.148	-.257
Adj. Log Wage	-.107	-.143	-.136	-.221

^aThe *t*-statistics of these differences are less than |2|. All other *t*-statistics exceed |2|.

populations. In 1940, the typical newly arrived immigrant had about .8 years more schooling than the typical native. This educational advantage decreased for subsequent waves, and by 1970, the typical newly arrived immigrant had slightly less schooling than natives. The decline in the relative schooling of immigrants accelerated during the 1970's, so that the most recent immigrants enumerated in the 1980 Census had .7 years fewer schooling than natives.

The trends in the relative immigrant wage show that recent immigrant waves have lower earnings capacities than earlier waves (see my 1985 article). Table 1 indicates that the skill decline can be observed over the entire postwar period. In 1940, the wage rate of recent immigrants was about 3.1 percent lower than that of natives. The wage differential increased to 12.8 percent by 1960, to 16.0 percent by 1970, and to 29.9 percent by 1980.

Finally, the data indicate that the deterioration in the immigrant wage cannot be explained by the relative decline in immigrant educational attainment (or by changes in other observable demographic characteristics). In 1940, the typical recent immigrant earned about 2.6 percent less than a demographically comparable native. The wage disadvantage of recent immigrants relative to comparable natives increased to 11.3 per-

cent in 1960, to 14.9 percent in 1970, and to 22.4 percent in 1980.

These intercensal comparisons implicitly assume that by differencing immigrant skills and wages from those of natives in the same calendar year, I net out the impact of the business cycle, of shifting skill prices, and of other macroeconomic fluctuations on the experiences of immigrants. It is unlikely that immigrants and natives respond equally to cyclical changes in the economy. For instance, it may be the case that immigrant wages are much more sensitive to economic downturns than those of natives. This hypothesis would explain why immigrant labor market performance lagged in 1980 (though the hypothesis would be hard-pressed to explain the 1940 data).

To ascertain the sensitivity of the results to the specification of period effects, I calculated the immigrant/native differentials using alternative reference groups. Panel B of Table 1 presents the differences between recent immigrants and young native men (aged 18–24). These two groups have one factor in common; both have just entered the U.S. labor market. If job opportunities for new labor market entrants are more sensitive to changing economic conditions, intercensal comparisons of recent immigrants that adjust for the changes experienced by young native men should provide better estimates of the secular trend.

Alternatively, one can argue that recent immigrants should be compared not to young native men, but to native men who are roughly in the same stage of the working life. A disproportionately large number of the recent immigrants in my sample are between the ages of 25 to 44 (in 1980, 85.5 percent of recent immigrants are in this age group as compared to 48.5 percent of natives). Hence an alternative base is the group of native men aged 25–44. Panel C of Table 1 reestimates the various differentials using these natives as the reference group.

Despite the major changes in the specification of period effects, the qualitative nature of the results is generally unaffected (the exception being the trend in the educational attainment of immigrants relative to that of young native men). The typical re-

cent immigrant in 1960 earned about 33.1 percent more than a young native man. The immigrant advantage over young natives declines to 24.9 percent in 1970 and to 21.5 percent in 1980. Between 1960 and 1980, the relative immigrant wage declined by about 12 percentage points. Similarly, recent immigrants in 1960 earned 12.6 percent less than natives aged 25–44. By 1970, the wage disadvantage had increased to 14.8 percent, and by 1980 to 25.7 percent. Between 1960 and 1980, the immigrant relative wage had fallen by 13 percentage points. In Panel A of Table 1, the decline in the relative immigrant wage over the 1960–80 period was 17 percent. It seems that accounting for differential period effects between immigrants and natives only slightly attenuates the downward trend in immigrant skills and labor market performance.

II. The Role of National Origin

Because of changes in immigration policy and in economic and political conditions both in the United States and abroad, the national origin mix of the immigrant flow during the 1970's was different than that of earlier waves. In the 1950's, over half of the immigrants originated in Europe, 39 percent originated in the Western Hemisphere, and 6 percent originated in Asia. In the 1970's, 18 percent originated in Europe, 44 percent originated in the Western Hemisphere, and 35 percent originated in Asia. There is substantial dispersion in the skills and labor market performance of different national origin groups (see my 1987 article). The results presented below indicate that the changing national origin mix of the immigrant flow largely explains the decline in skills documented in the previous section.

The immigrant population is divided into 41 national origin groups, as well as a residual "other" category. (My 1987 article lists the 41 countries.) The 41 groups account for over 90 percent of the 1951–80 immigrant flow. For each of the 42 groups (including other immigrants), I calculated the average educational attainment and log wages.

Let Y_t be the average value for a particular characteristic observed in the recent im-

migrant population in year t (relative to that observed among natives aged 25–64). By definition, Y_t can be written as

$$(1) \quad Y_t = \sum_j p_{jt} y_{jt},$$

where y_{jt} is the average value observed among recent immigrants from national origin group j in year t (relative to natives); and p_{jt} is the fraction of the immigrant flow in year t originating in country j .

It is useful to define the value that would have been observed if a different national origin mix had migrated to the United States, such as the national origin mix observed at time τ , $p_{j\tau}$:

$$(2) \quad Y(t, \tau) = \sum_j p_{j\tau} y_{jt}.$$

The impact of a changing national origin mix is then given by

$$(3) \quad Y_t - Y(t, \tau) = \sum_j y_{jt} (p_{jt} - p_{j\tau}).$$

I wish to determine the extent to which the changing national origin mix explains the decline in immigrant skills. In other words, how important is the change predicted by equation (3) in terms of the total change? Because the data on y_{jt} can be chosen arbitrarily from any of the censuses, there are a number of answers to this question. To easily summarize the evidence, I use the vector y_{jt} estimated from the 1980 Census. The selection of alternative vectors does not alter the qualitative nature of the results.

Table 2 reports the results of simulations using this framework.⁵ Consider the evidence regarding educational attainment. As I documented earlier, the average schooling of recent immigrants (relative to natives) fell by 1.1 years between 1960 and 1980, and by .4 years between 1970 and 1980. Using

⁵Because of the small number of immigrants during the 1930's, Table 2 focuses on explaining the changes observed between 1960 and 1980.

TABLE 2—DECOMPOSITION OF CHANGES IN IMMIGRANT SKILLS (RELATIVE TO NATIVES)

Variable	Change: 1960–1980		Change: 1970–1980	
	(1)	(2)	(1)	(2)
<i>Education</i>	–1.075	–.932	–.442	–.215
<i>Log Wage</i>	–.171	–.213	–.139	–.066
<i>Adj. Log Wage</i>	–.111	–.147	–.075	–.024

Note: Col. (1) is total change; Col. (2) is change due to national origin.

equation (3), I estimate that the observed changes in national origin would have led to a decline in the educational attainment of $-.9$ years between 1960 and 1980, and $-.2$ years between 1970 and 1980. Put differently, at least half of the drop in educational attainment can be accounted for by changes in the national origin mix of immigrant flows.

The data also indicate that the relative wage of newly arrived immigrants fell by 17.1 percentage points between 1960 and 1980, and by 13.9 percentage points between 1970 and 1980. I estimate that changes in national origin alone would have caused a drop in the relative immigrant wage of 21.3 percentage points between 1960 and 1980, and of 6.6 percent between 1970 and 1980. Changes in national origin, therefore, explain at least two-thirds of the wage decline over this period.

Finally, the data show an 11.1 percentage point drop in the adjusted immigrant wage between 1960 and 1980, and a 7.5 percentage point drop between 1970 and 1980. The changing national origin mix of immigrants account for over a third of the decline in adjusted wages.

In sum, shifts in the national origin mix of the immigrant flow are responsible for a substantial decline in immigrant skills and for a deterioration in the labor market performance of successive immigrant waves over the postwar period. In effect, the typical immigrant originating in the source countries responsible for immigration in the

1970's is less skilled than the typical immigrant originating in the source countries responsible for immigration in the 1950's and early 1960's.

III. Skill Transmission Across Immigrant Cohorts

Consider the regression model:

$$(4) \quad y_{jt} = \alpha_0 + \alpha_1 y_{j,t-1} + \varepsilon_{jt},$$

where y_{jt} is the educational attainment or wage of an immigrant cohort from country j that arrived in the United States at time t . The specification in equation (4) raises the question of whether immigrant skills are transmitted across cohorts. This transmission may occur because most immigrants arriving in the United States already have relatives residing here. It is likely that information regarding the U.S. labor market is relayed across the links in the immigration chain. This would suggest that immigrant cohorts that were particularly successful in the U.S. labor market would be followed by cohorts that would also be relatively successful.

The problem with testing the hypothesis underlying equation (4) is that a positive estimate of α_1 may have nothing to do with the transmission of skills, and may be entirely due to a fixed effect that characterizes the national origin group. The correct statistical model is then given by

$$(5) \quad y_{jt} = \alpha_0 + \alpha_1 y_{j,t-1} + v_j + \delta_{jt},$$

where v_j is the national-origin fixed effect.

For each of the 41 countries in the analysis, I have information on the skills and wages (relative to natives) of three successive waves: the 1955–59, the 1965–69, and the 1975–79 arrivals. The data is pooled across censuses, so that the skills of the 1965–69 immigrants are related to those of the 1955–59 wave, while the skills of the 1975–79 immigrants are related to those of the 1965–69 wave. The pooling yields 82 observations and allows the estimation of a fixed-effects model. Because of period ef-

TABLE 3—SKILL TRANSMISSION ACROSS IMMIGRANT COHORTS

Dependent Variable	y_{t-1}	Controls for Fixed Effects	R^2
Education	.8690 (16.54)	No	.780
Education	.2081 (1.29)	Yes	.933
Log Wage	.8230 (11.29)	No	.633
Log Wage	.2911 (2.46)	Yes	.887
Adj. Log Wage	.6105 (7.59)	No	.466
Adj. Log Wage	.1454 (1.65)	Yes	.885

Note: The t -ratios are shown in parentheses. All regressions also include an intercept and a dummy variable indicating if the dependent variable was drawn from the 1980 Census.

fects, the regression also includes a dummy variable indicating if the dependent variable is drawn from the 1970 or 1980 Census.

Table 3 presents the estimated regressions. Without controlling for the fixed effects, there exists a strong positive correlation in Education, Log Wages, and Adjusted Log Wages across cohorts. After controlling for fixed effects, there remains a positive correlation between Wages and Adjusted Log Wages across cohorts, and an insignificant relationship between educational attainment across cohorts. This pattern of coefficients suggests that there is skill transmission across cohorts. After all, educational attainment at the time of ar-

rival (for prime-age men) is difficult to transmit, and the fixed effect should account for the correlation in schooling across successive waves. In contrast, labor market success in the United States (as measured by the wage rate) can be transmitted, and the evidence indicates that it is. Note also that the transmission coefficient is less than unity, indicating a regression towards the mean across successive waves.

In view of the relatively small number of observations and of the importance of fixed effects, it is best to interpret the results with caution. They do suggest, however, that the future study of the transmission of skills within immigrant households may provide important insights into the labor market performance of the foreign-born in the United States.

Immigration and Wages: Evidence from the 1980's

By KRISTIN F. BUTCHER AND DAVID CARD*

More immigrants entered the United States during the past decade than in any comparable period since the 1920's. Among the issues raised by this influx, none is as controversial as its effect on the labor market opportunities of native-born workers. Evidence on the labor market consequences of immigration is limited (see Michael Greenwood and John McDowell, 1986, and George Borjas, 1990). This paper presents new evidence on the effects of immigration, based on changes in the distributions of wages in 24 major cities during the 1980's. Although immigrant inflows are small relative to the populations of most cities, recent immigrants are a significant fraction of less-educated workers in many cities. We therefore concentrate on measuring the effects of immigration at the lower tail of the wage distribution. In particular, we ask whether recent declines in the real earnings of the least-skilled workers in the U.S. economy are related to immigration. Our empirical analysis reveals large differences across cities in the relative growth rates of wages for low- and high-paid workers. Nevertheless, these differences bear little or no relation to the size of immigrant inflows. Our results therefore confirm the findings of earlier studies, based on 1970 and 1980 Census data, that suggest that the labor market consequences of higher immigration are relatively small.

I. Characteristics of New Immigrants in 1980 and 1985

A standard approach to measuring the labor market effects of immigration is to treat different cities within the United States as distinct labor markets, and to compare labor market outcomes across cities with higher and lower immigrant densities. We

follow this approach here, tracking wages in 24 major cities during the period from 1979 to 1989. Our sample includes the 10 most immigrant-intensive cities identifiable in *Current Population Survey (CPS)* microdata files, along with a group of 14 other cities (listed in Table 2). The other cities were selected by a variety of criteria, including stable boundaries, relatively large sample sizes, and a desire for geographic comparability with the high-immigrant cities. We believe that the sample gives a fair picture of the variation in immigrant inflow rates and relative immigrant "quality" across major U.S. cities.

We begin by presenting some simple evidence on the nature of recent immigrant inflows into the United States. The first two columns of Table 1 contain data from the 1980 Census on the characteristics of natives and recent immigrants (i.e., those who immigrated between 1975 and 1980) in the 24 cities in our sample. Recent immigrants are younger, less educated, and more likely to be male than natives (or earlier immigrants). The proportion of Hispanics is also much higher among recent immigrants than in the native population. The education distribution of newly arriving immigrants is relatively disperse: the fraction of college graduates is about the same as in the native population, but close to one-quarter of recent immigrants have less than an elementary education. As a result, recent immigrants make up 17 percent of the population in these cities with 6 or fewer years of schooling, and 10 percent of the population with less than an eighth-grade education.

Columns 3 and 4 of Table 1 present the characteristics of individuals in the March 1985 *CPS*, classified by whether or not the respondent was living in the United States 5 years earlier. Based on responses to a similar question in the 1980 Census, we estimate that 85 percent of those living abroad 5 years ago are immigrants. Demographic differences between the two groups

Avg. Log Wage	1.82	1.51	2.06	1.75
Std. Deviation	0.66	0.66	0.66	0.64

Note: Samples contain individuals age 16–68 in 24 cities. Col. (1) contains natives; Col. (2) contains immigrants who entered the United States between 1975 and 1980; Col. (3) contains individuals who were living in the United States in March 1980; Col. (4) contains individuals who were living abroad in March 1980.

are consistent with the differences between recent immigrants and others in the 1980 Census. The 30 percent wage gap between the new arrivals and other workers is also very similar to the gap between recent immigrants and others in 1980. We conclude from these comparisons that the relative “quality” of arriving immigrant cohorts was relatively stable between 1975 and 1985.

II. Immigration to Specific Cities

From this general overview we turn to a specific examination of the nature of immigrant flows to each of the 24 cities in our data set. Table 2 provides information on the percent of “recent immigrants” in each city in 1980 and 1985, together with data on the overall population growth rate between 1980 and 1987, and the wage gap between recent immigrants and natives in 1980. Two important features of U.S. immigration are highlighted in the table. First, recent immigrants are highly concentrated in only a few cities. Three cities (New York, Los Angeles, and Miami) accounted for 51 percent of recent immigrants in both 1980 and 1985. Second, there is substantial variation across

TABLE 2—CHARACTERISTICS OF 24 MAJOR CITIES

	Percent Recent Imms:		Growth Rate ^a	Wage Gap ^b
	1980	1985		
New York	4.4	6.0	0.4	34.5
Los Angeles	7.7	7.3	1.8	44.5
Chicago	2.5	2.4	0.3	32.3

^aAnnual percentage growth rate in population 1980–87.

^b1980 wage gap between recent immigrants and native born.

cities in the composition of recent immigrant inflows. As a general rule, the quality of recent immigrants, measured by their wage gap relative to native workers, is lower in cities with higher inflow rate. A key correlate of both inflow rates and the relative wage of recent immigrants is the fraction of Hispanic immigrants, which ranges from under 10 percent in Detroit, Minneapolis, Seattle, and Portland to over one-half in cities in California and Texas.

An important feature of immigration to a local labor market is its effect on population growth. A natural assumption is that an inflow of new immigrants generates a proportional increase in the labor force and population of a city. Recent research by Randall Filer (1990), however, suggests that the intercity migration decisions of native workers are highly sensitive to immigrant inflows. Indeed, Filer’s analysis of population movements between 1975 and 1980 im-

plies that immigrant arrivals are almost completely offset by native outflows.

There is some evidence of offsetting out-migration in Table 2, particularly for the high-immigrant cities of New York, Los Angeles, and Miami. All three cities had large immigrant inflows but relatively modest growth rate during the 1980's. In the absence of out-migration, an increase in the fraction of new immigrants will raise the population growth rate of a city point-for-point. Therefore, if native inflow rates are independent of immigration rates, population growth rates should be linearly related to immigration inflow rates, with a slope of 1.0. In fact, the slope of a regression line fitted to all 24 cities in our data set is 1.04 (with a standard error of 0.54). When a similar regression is fit to the subset of observations that excludes New York, Los Angeles, and Miami, however, the estimated slope is much higher (2.76, with a standard error of 0.67). This regression accounts for about one-half of the variation in growth rates in the subset of 21 cities. From this evidence we conclude that native in-migration flows during the 1980's were actually *positively* correlated with inflows of recent immigrants to all but the 3 most immigrant-intensive cities.

One explanation for the difference between the highest-immigrant cities and other major cities is based on the composition of immigrant inflows. Between 1980 and 1985, over one-half million Cuban and Southeast Asian refugees arrived in the United States (Frederick Hollmann, 1990, Table V). Most of the Cubans, and perhaps one-half of the Asians, settled in either New York, Los Angeles, or Miami. To the extent that the refugees were drawn to these cities by cultural and ethnic ties, their location decisions may have been less sensitive to local labor market conditions than the decisions of other newly arriving immigrants. It should be pointed out, however, that New York and Los Angeles had large immigrant inflows during the 1970's and grew more slowly than most other U.S. cities between 1970 and 1980. The experiences of these two cities during the 1980's were therefore in keeping with earlier trends. What is appar-

ently different between the 1970's and 1980's is the emergence of a positive relation between immigration and overall population growth among other cities.

III. Immigration and Wages

Table 3 turns to an examination of wage outcomes in different cities during the past decade. The data are taken from merged files of the 12 monthly *Current Population Surveys* administered in 1979, 1980, 1988, and 1989, and pertain to hourly wage rates (for hourly rated workers) or the ratio of average weekly earnings to average weekly hours (for salaried workers). For each city and each year, we have calculated the 10th and 90th percentiles of the log wage distribution. The first two columns of Table 3 represent (unweighted) averages of the 1979 and 1980 percentiles, and the second two columns represent changes from the 1979-80 average to the 1988-89 average.

TABLE 3—LEVELS AND CHANGES IN PERCENTILES OF LOG WAGES IN 24 CITIES: 1979-80 TO 1988-89

	Percentiles in 1979-80		Changes from 1979-80 to 1988-89	
	10th	90th	10th	90th

Washington, D.C.	1.18	2.69	0.43	0.41
Baltimore	1.12	2.39	0.36	0.54
Houston	1.14	2.45	0.22	0.52
Minneapolis	1.15	2.47	0.39	0.50
Dallas	1.14	2.35	0.28	0.58
Seattle	1.27	2.50	0.29	0.49
Anaheim	1.14	2.55	0.40	0.50
Milwaukee	1.12	2.39	0.30	0.46
Atlanta	1.12	2.40	0.39	0.58
San Diego	1.12	2.44	0.36	0.52
Miami	1.10	2.20	0.29	0.63
Denver	1.15	2.50	0.29	0.45
Riverside, CA	1.12	2.41	0.37	0.58
San Jose	1.25	2.63	0.40	0.58
New Orleans	1.13	2.36	0.19	0.49
Tampa	1.10	2.17	0.29	0.59
Portland	1.19	2.46	0.29	0.44
Sacramento	1.12	2.46	0.43	0.48

The distribution of hourly wages in each city is approximately lognormal, although the distributions contain prominent "spikes" at points like \$3.00, \$5.00, and \$10.00 per hour. The spread between the 10th and the 90th percentile of log wages in any city tends to be strictly proportional to the estimated standard deviation, as is the case for a normal distribution.

The 1979–80 data reveal sharp differences across cities in both the level and dispersion in wages. Interestingly, there is less variation across cities in the 10th percentile of wages than in wages at the middle or upper end of the earnings distribution. This is apparently due to the restraining effect of the minimum wage, that served as the 10th percentile of wages in many cities in 1979 and 1980. One implication of a binding national wage floor is that the dispersion of wages within a city is highly correlated with the average level of wages. In 1979–80, this pattern is clearly present in the data. Despite the differences in mean log wages across cities, however, 97 percent of the overall variation in individual wages for workers in our sample of cities is within-city variation.

Intercity differences in the 10th percentile of wages in 1979–80 are uncorrelated with differences in the fraction of recent immigrants (or total immigrants) in the city. Wages at the upper end of the earnings distribution are weakly negatively related to the fraction of recent immigrants, but weakly positively related to the overall fraction of immigrants. These small and unsystematic correlations are consistent with findings in the previous literature. Looking across cities in 1979–80, there is no evidence of any effect of immigration on the level of wages.

Changes in the distribution of wages over the last decade also show considerable intercity variation. Mean log wages in most cities grew at roughly the same rate as the Consumer Price Index (CPI), which rose 44 percent between 1979–80 and 1988–89. Mean log wages in Detroit, Houston, and New Orleans, however, grew much more slowly than average consumer prices, while those in New York grew faster. As shown in the third and fourth columns of Table 3,

FIGURE 1. IMMIGRATION AND CHANGE IN WAGE DECILES IN 24 MAJOR CITIES, 1979–80 TO 1988–89

there are significant differences across cities in the relative growth of the 10th and 90th percentiles of wages (and in the corresponding change in the standard deviation of wages). In every city except Washington, D.C., wage rates in the upper tail of the earnings distribution grew more quickly than those in the lower tail. Thus, the growth in wage inequality during the 1980's (Chinhui Juhn et al., 1989) was almost entirely due to an increase in the within-city variance.

The rise in wage inequality over the 1980's was greater in cities with relatively bigger immigrant inflows. This is illustrated in Figure 1, which plots the changes in the 10th and 90th percentiles of wages for each city against the fraction of recent immigrants in 1985. Contrary to our expectations, however, the data suggest that higher immigration is associated with more rapid increases in the 90th percentile of wages, rather than with any relative decline in the 10th percentile of wages.

One explanation for the pattern of the data in Figure 1 is that the cost of living rose more rapidly in cities with larger immigrant inflows, and that these increases in

prices lead to wage increases for high-wage workers. To test this possibility we constructed wage changes relative to city-specific cost-of-living indexes, which are available from the Bureau of Labor Statistics for most of the cities in our sample. As hypothesized, the change in the city-specific cost of living is positively correlated with the fraction of recent immigrants in 1985. Adjusting for changes in the local cost of living, the change in the 90th percentile of wages is still positively related to the fraction of recent immigrants, but the regression coefficient is halved and falls to statistical insignificance. Similarly, an adjustment for the local cost of living causes the regression coefficient relating the change in the 10th percentile of wages to the fraction of recent immigrants in 1985 to become (slightly) negative. Thus, adjusting for city-specific changes in the cost of living, we find less evidence of a positive correlation between immigration rates and the growth of high-skilled wages, and more evidence of a negative correlation between immigration and the growth of low-skilled wages. Neither of these correlations, however, is large or statistically significant.

We have also calculated the effect of higher immigration on the various percentiles of the wage distribution, controlling for such factors as the overall population growth rate, the fraction of immigrants initially living in each city, and the initial level of wages in the city. In no case do we find a large or statistically significant effect of immigration on the rate of increase of wages for the least-skilled workers.

IV. Conclusions

We believe that the evidence we have assembled for the 1980's confirms the conclusions from earlier studies of 1970 and

1980 Census data. In particular, we find little indication of an adverse wage effect of immigration, either cross sectionally or within cities over time. Even for workers at the 10th percentile of the wage distribution there is no evidence of a significant decline in wages in response to immigrant inflows. The one important difference that emerges between our analysis and earlier studies is the finding of a positive link between immigrant inflows and net native migration. During the 1980's, rapidly growing cities in Texas, Florida, and California attracted both native and newly arriving immigrant workers. This configuration is quite different from the pattern of offsetting immigrant and native population inflows identified by Filer in earlier data.

Immigrants in the American Labor Market: Quality, Assimilation, and Distributional Effects

By ROBERT J. LALONDE AND ROBERT H. TOPEL*

Immigration to the United States during the 1970's and 1980's was greater than in any decade since the 1920's. Simultaneously, the proportion of immigrants arriving from Europe or English-speaking countries declined dramatically from 46 percent in the 1960's to only 13 percent in the 1980's. These changes in the pace and composition of immigrant flows have raised three main concerns that have dominated recent literature and policy discussions. First, are recent immigrants less prepared to succeed in the U.S. labor market than their predecessors? The typical new immigrant may bring skills (including language, culture, and educational attainment) that are less attuned to the American market. Further, this decline in immigrant "quality" may have been magnified by immigration reforms of the 1960's, that gave less weight to individuals' skills in admission decisions. Thus average immigrant quality may have also declined *within* ethnic groups. Second, do new immigrants recover from their initial earnings disadvantage? As a policy issue, if new immigrants do not assimilate, the increased immigrant flows may place additional burdens on public welfare systems, while exacerbating other social problems associated with persistent poverty.

The third concern is the distributional impact of immigration on natives' welfare. To the extent that immigrant and native skills are substitutable, increased immigration may reduce natives' earnings and employment prospects. In fact, the 1970's and 1980's were periods of declining real wages and rising unemployment among less-skilled

American workers. These facts have motivated policy proposals and legislation designed to curtail the entry of low-wage immigrants to the United States, while giving greater emphasis to skill-based criteria in admissions decisions.

This paper provides evidence on immigrants' performance and impact in the U.S. labor market. We document that new immigrants do bring fewer marketable skills to the United States than did earlier cohorts, and that changes in the source countries of recent immigrants account for all of this decline in immigrant "quality." We find no important evidence that quality has declined *within* immigrant ethnic groups. We also show that immigrants assimilate rapidly in the U.S. market (10 years of U.S. experience offsets most of the earnings disadvantage of new immigrants), and that assimilation is more rapid for groups who start with lower initial wages.

These findings imply that immigrants' long-run earnings potential is similar to that of ethnically similar natives. In this sense, we think that fears about declining immigrant quality have been exaggerated. We present additional evidence that increased immigration has had a negligible impact on U.S. workers' wages and employment prospects. Taken together, these results suggest that recent changes in the rate and composition of immigration will not have serious long-run effects on the U.S. labor market.

I. Changes in Immigrant Quality

Recent studies (see George Borjas, 1985; Barry Chiswick, 1986) indicate a decline in the labor market skills of recent immigrants to the United States. There are two possible sources for this decline. First, non-European immigrants may arrive with fewer skills. Second, even absent changes in source

and 1980, new immigrants' schooling increased overall, but declined relative to natives. Simultaneously, new immigrants' earnings disadvantage rose by an additional 15 points, to 35 percent (col. 3). In this sense, the average (relative) "quality" of new immigrants declined during the decade, even though average schooling levels suggest no decline in quality *within* immigrant groups.

The evidence in Table 1 suggests that change in source countries and changes in average years of native schooling may account for the decline in relative immigrant earnings. To test that proposition, we recalculated the relative earnings of 1970 immigrants, but we weighted each immigrant group by the group's relative share among new immigrants in 1980. We also reweighted natives' earnings to reflect their 1980 distribution of completed schooling. The calculations show that if the distribution of immigrants across source countries had been the same in 1970 as in 1980, and if educational attainment of U.S. workers had been the same in 1970 as in 1980, the relative earnings of immigrants in 1970 would have been at their 1980 level. For example, persons in the United States less than 5 years in 1970 would have earned 35 percent less than comparable natives, which is identical to the 1980 earnings gap. This indicates that the main factor affecting the relative earnings of new immigrants is simply where they come from. There is no evidence of declining quality *within* immigrant ethnic groups.

II. Assimilation of Immigrants

countries, average productivity may decline *within* immigrant groups when changes in laws and incentives favor the entry of less-skilled individuals.

To address the question of declining immigrant quality, Table 1 compares recent immigrants' and natives' earnings and education in the 1970 and 1980 Censuses. In 1970, the average new immigrant arrived in the United States with 10.8 years of completed schooling, and earned about 20 percent less than natives with similar labor market experience (col. 1). Between 1970

The evidence in Table 1 suggests that average immigrant quality (as measured by earning capacity) declined in the 1970's. Since Asia and Latin America remained the most important sources of (legal and illegal) immigration during the 1980's, there is little doubt that the decline in the earning capacity of new immigrants has continued. But since immigrants assimilate with time in the United States, the decline in new immigrants' *initial* earning capacity overstates the long-term decline in immigrant quality. Further, those groups with the largest initial

earnings disadvantage assimilate the most. Thus an increase in the shares of Asians and Hispanics among new immigrants reduces new immigrants' relative earnings, but increases the average rate of assimilation.

These points are also demonstrated in Table 1. The cohort of immigrants who arrived in the United States between 1965 and 1969 (1–5 years in the United States in 1970) earned 20 percent less than comparable natives in 1969. By 1979, that cohort had been in the United States for 11–15 years and they earned 14 percent less than comparable natives, so relative earnings grew by 7 percent over the decade. This growth is the average of assimilation rates within immigrant groups. The table shows that assimilation is much larger among Asians and Hispanics than among Europeans, who were the largest immigrant group in 1970. Europeans who arrived between 1965 and 1969 experienced no relative earnings growth at all during the 1970's, but they also started from parity in 1969. By comparison, Asians and Mexicans experienced relative earnings growth of 24 and 20 percent over the decade, respectively. Since Asians and Mexicans accounted for vastly larger proportions of new immigrants in the 1970's and 1980's, the rate of convergence between immigrant and native earnings will be correspondingly larger than in the past.

Rapid earnings growth does not mean that assimilation eliminates the earnings gap between immigrants and natives. Nor should we expect the gap to be eliminated, since there are important earnings differentials among *natives* of different ethnic backgrounds. To illustrate, column 1 of Table 2 reports estimated wage differentials among natives of various ancestry, based on cross-sectional data from the 1980 Census. Since these estimates control for the usual list of observable background characteristics, the reported values are approximate percentage differentials between the earnings of the indicated ethnic group and European-Americans with the same observable characteristics. As the table shows, a typical Mexican-American earns about 11 percent less than a comparable European, while an Asian-American earns about 7 percent less.

TABLE 2—RATES OF IMMIGRANT ASSIMILATION

Ethnic Group	(1)	(2)	(3)	(4)	(5)

Source: Calculations using 1970 and 1980 U.S. Census Microdata files and our paper (1991b, Table 5).

Note: Col. (1) = log wage differences for ethnic natives; Col. (2) = initial gap with ethnic natives; the rates of assimilation in cols. (3), (4), and (5) are relative to: Col. (3) ethnic natives 1980 cross section; Col. (4) old immigrants 1980 Cross Section; Col. (5) old immigrants 1970–80 panel.

Estimates control for years of completed schooling, a quartic in experience, and interactions between schooling and experience. Additional controls do not affect the results. Assimilation rates estimate the effect of the first 10 years' U.S. experience on wages, measured relative to observationally identical ethnic natives and ethnic immigrants who have been in the U.S. for more than 30 years. Standard errors are in parentheses.

In our view, these estimates suggest that the relevant question is not whether immigrants catch up with the modal native (who has European ancestry), but rather whether they catch up to natives of similar ancestry to their own.

To frame this question more precisely, consider the following decomposition of the regression-adjusted wage differential between immigrants from arrival cohort i in census year t and natives of similar ethnicity:

$$(1) \quad \varepsilon_{it} = a_{it} + b_{it} + u_i,$$

where the parameters a_{it} represent the average level of accumulated, U.S.-specific, human capital embodied in members of arrival cohort i during year $t = 1970$ or $t = 1980$. Assimilation occurs when the relative human capital of an immigrant cohort rises with time spent in the United States, $a_{it} < a_{i,t+10}$. Identification of this from estimates

of ε_{it} is complicated by the appearance of b_{it} , that represents the impact of aggregate labor market conditions on immigrant cohort i 's earnings, and by u_i , that represents the cohort-average value of other unobserved factors (immigrant "quality") that affect productivity. Based on (1), two possible estimators of immigrant assimilation are possible. From a single cross section, say $t = 1980$, we can estimate the effect of 10 years residence in the United States by comparing the relative earnings of persons who arrived between 1975 and 1979 ($i = 75$) to the earnings of similar immigrants who arrived between 1965 and 1969 ($i = 65$):

$$(2) \quad \varepsilon_{65,80} - \varepsilon_{75,80} = a_{65,80} - a_{75,80} + b_{65,80} - b_{75,80} + u_{65} - u_{75}.$$

This provides unbiased estimates of assimilation only if (i) there are no time effects on relative earnings of the two cohorts, $E(b_{65,t} - b_{75,t}) = 0$, and (ii) the cohorts have the same average talent, $E(u_{65} - u_{75}) = 0$. For example, when the average quality of successive immigrant cohorts declines, $u_{65} > u_{75}$, equation (2) will overstate the rate of immigrant assimilation. This issue underlies Borjas's 1985 criticism of Chiswick's 1978 estimates of assimilation.

The alternative to (2) is to form a quasi panel by following the wage growth of a single cohort between the 1970 and 1980 Censuses. For the cohort that arrived between 1965 and 1969, this estimate is

$$(3) \quad \varepsilon_{65,80} - \varepsilon_{65,70} = a_{65,80} - a_{65,70} + b_{65,80} - b_{65,70}.$$

This estimator of assimilation will be unbiased if aggregate market conditions do not change the cohort's relative earning power, $E(b_{65,80} - b_{65,70}) = 0$. Our estimates of (3) use earlier immigrants and natives of the same ethnicity as recent immigrants as normalizing groups. If recent immigrants' human capital substitutes for that of ethnically similar earlier immigrants or natives, the identifying condition is likely to be satisfied.

As shown by Table 2, both estimates of assimilation indicate that most of new immigrants' earnings disadvantage is eliminated after only 10 years' experience in the U.S. labor market. Column 2 shows the initial difference in log weekly wages between immigrants who arrived between 1975 and 1979 and natives of the same ethnicity. New immigrants' wages typically start out well below those of natives. But the data show that this earnings disadvantage rapidly narrows. Column 3 and 4 show estimates of 10 years' assimilation, based on applying (2) to cross-sectional data from the 1980 Census. Although the two sets of estimates rely on different normalizing groups, they nevertheless indicate rapid and nearly identical rates of immigrant assimilation. Both estimates indicate that Asian immigrants will overcome 75 percent ($= .24/.32$) of their original wage shortfall after 10 years in the United States. Other groups show similar patterns of strong assimilation. Notice that the largest wage gains occur for groups with the largest initial wage gap.

These estimates are subject to the criticism that immigrant quality may have fallen over time within ethnic groups. That decline would cause (2) to overstate the rate of assimilation. Although our estimates in Table 1 showed no evidence of declining immigrant quality within ethnic groups, the "panel" estimator in (3) avoids this concern by following the earning growth of a fixed cohort over time. As shown in column 5, panel estimates confirm that declining immigrant quality within ethnic groups is not an important issue: estimates of assimilation are large, and they are nearly identical to the cross-sectional estimates shown in column 4. We conclude that immigrants assimilate rapidly in the U.S. labor market.

III. The Effects of Increased Immigration on Wages and Employment

Immigrant flows accounted for only about 5 percent of growth in aggregate labor supply during the 1970's and 1980's. At this level of aggregation it is difficult to argue that immigration had important effects on natives' wages and employment prospects.

Yet immigration is heavily concentrated in certain geographic areas and among certain skill groups. For example, during the 1970's immigrants accounted for nearly two-thirds of labor force growth in Los Angeles, and over one-third of growth in Miami. This concentration raises the possibility of significant distributional effects on some natives' wages, at least in the short run. In light of these facts, we have argued elsewhere (1991a) that the largest impact of immigration on wages and employment must be for individuals who are good substitutes for new immigrants in terms of both location and skills. In our analysis, these individuals are other current and past immigrants of similar ethnicity, as well as less-skilled natives located in areas that have experienced large immigration flows.

As shown by Table 3, our estimates indicate that increased immigration has had relatively small effects on recent immigrants', and on young black and Hispanic natives', wages and earnings. The econometric framework for isolating these effects is spelled out in our 1991a paper. Briefly, the estimates are derived by comparing the *relative* wages of the indicated groups among SMSAs with varying amounts of immigration, while controlling for a host of background characteristics. As above, there are two approaches to estimating these effects. The first column of Table 3 shows estimates derived from cross-sectional data in the 1980 Census, while the second column shows panel estimates derived from relative wage *changes* within SMSAs with varying immigration flows during the 1970's.

Several aspects of these results are noteworthy. First, even the largest of the crowding effects we estimate is small. For example, as shown in panel A, a 100 percent increase in the rate of new immigration (0-5 years since entry) to the typical SMSA reduces the wages of new immigrants by only 2.4 percent. Second, the wage penalty for membership in a large immigration cohort is smaller for immigrants who have been in the United States longer. This suggests that as immigrants assimilate they "melt" into the U.S. labor market by becoming better substitutes for natives. This is

TABLE 3—THE EFFECTS ON WEEKLY WAGES OF A 100 PERCENT INCREASE IN THE SIZE OF AN IMMIGRATION COHORT

Notes: Estimates reflect the change in log earnings or weekly wages for the indicated group, relative to immigrants in an SMSA who had been in the United States 30 years or more. Effects on natives refer to the impact of a change in post-1965 immigration on black or Hispanic earnings. The characteristics controlled for are years of schooling, potential experience, marital status, number of children, disability status, race and ethnicity, occupation, and industry.

important, since it implies that immigration's effects on natives, who by definition are fully assimilated, are likely to be negligible. This point is confirmed in panel B of Table 3, where we report estimated effects of new immigration on the wages of young native black and Hispanic men, whose skills may be most substitutable for those of immigrants. These effects are smaller than the direct effects in panel A, and we regard them as economically negligible.

The foregoing estimates reflect immigration's impact on wages, leaving open the possibility that there are larger effects on employment and unemployment. One way of testing this possibility is to replicate the preceding analysis, but replacing log weekly

wages with log annual earnings (wages times weeks worked). Our 1991a paper shows that the estimates in panel A are virtually unchanged by this procedure, which implies that all of immigration's impact on earnings comes through its effect on wages; weeks of employment are unaffected. Over all, we have been unable to adduce any evidence of important distributional effects of immigration on wages and employment.

IV. Conclusion

At a time when new immigrants are entering the United States in the largest numbers in recent history, wages and employment prospects of less-skilled Americans have fallen dramatically. At the same time, new immigrants' earnings have fallen, raising questions about the long-term quality of new immigrant waves. It is tempting to see a connection between these facts and to advocate changes in policies that affect the quantity and quality of new immigrants to the United States.

Our evidence suggests that these policy concerns are exaggerated. It is true that immigrant quality, as measured by initial earnings, has declined as source countries have shifted toward Asia and Latin America. But these immigrants assimilate rapidly, and our result suggests that their long-run earning potential will be much like ethnically similar natives. Thus the long-run impact on productivity and income distribution will be much smaller than indicated by the initial earnings data. Further, although it is true that immigration has small effects

on equilibrium wages, virtually all of this burden falls on immigrants themselves. Labor market effects for nonimmigrants are negligible. Taken together, these results suggest that any adverse effects of current immigration flows on the U.S. labor market and on native welfare will be small.

THE HISTORY OF AFRICAN-AMERICAN ECONOMIC THOUGHT AND POLICY[†]

W. E. B. Du Bois and the Historical School of Economics

By THOMAS D. BOSTON*

William Edward Burghardt Du Bois was born in Great Barrington, Massachusetts, in 1868, and died in Ghana in 1963. He was a charter member of the NAACP, founder of the Pan African movement, and distinguished scholar on black life in America. Today, he is considered the father of the modern civil rights era. While most researchers are familiar with his scholarly contributions in history and sociology, few are aware of his studies in political economy.¹ Du Bois was the first African-American to pursue the Ph.D degree in economics. My objective is to acquaint the reader with this unusual individual, and to discuss his contribution to political economy and the Historical School of Economics that influenced it.

I. Historical Background

Du Bois received B.A. degrees from Fisk University in 1888 and Harvard University in 1890. Upon graduation, he entered Harvard's Ph.D program in history and political economy. His last two years of graduate study, 1892-94, were spent in residence at the University of Berlin. During this period,

Germany attracted many of America's leading graduate students. But, more importantly, the Political Economy Department at the University of Berlin was at the center of the famous "Methodenstreit," or Battle of Methods.

By 1880, the Historical School of Economics had reached its zenith under the influence of Gustav von Schmoller, J. Spiethoff, W. Sombert, A. Wagner, and M. Weber. Then in 1883, Carl Menger published a broadside assault on this school's methodology and ignited the "Methodenstreit." This battle pitted economists who employed the inductive, interdisciplinary method of research against the marginalist theoreticians led by Menger, Walras, and Jevons.

Du Bois entered the Department of Political Economy at Berlin during the high point of the Methodenstreit and his graduate supervisor was none other than Schmoller, the intellectual leader of the Historical School. His course work included theoretical political economy and industrialism and society from Schmoller and Wagner. Additionally, he sat through lectures by Max Weber and enrolled in Schmoller's research seminar.

These three professors had a profound influence upon Du Bois. In fact, Francis Broderick (1971) credits Schmoller with drawing Du Bois away from history and into political economy, and inspiring him to devote his career to scholarly research. Several years earlier, the faculty of Fisk University had nurtured Du Bois' lifelong commitment to resolving the "race problem." Now, the University of Berlin offered him the necessary methodological tools.

While studying at Berlin, Du Bois prepared a research paper that was to be pub-

[†]*Discussants:* William A. Darity, Jr., University of North Carolina-Chapel Hill; Bernadette Chachere, University of California-San Francisco.

*Associate Professor of Economics, School of Economics, Georgia Institute of Technology, Atlanta, GA 40332.

¹Herbert Aptheker (1980), Du Bois' biographer, has compiled a bibliography of his scholarly articles, essays and editorials that consumes several hundred pages; included among these are 21 books and 16 edited volumes. Du Bois' publications in political economy are concentrated between the years of 1896 and 1906.

lished in Schmoller's *Yearbook*.² Additionally, Schmoller took the unusual step of petitioning the university to admit Du Bois to Ph.D candidacy after only three semesters of study, one-half the minimum time required. In his *Autobiography*, Du Bois observed:

Schmoller wanted to present me for my doctorate, despite the fact that I had not finished the "triennium" required in a German university and my work at Harvard was not recognized. The faculty was willing in my case but was restrained by the professor of English who threatened to push the similar claims of several Britishers. I therefore regretfully had to forego the chance of a German doctorate and wait for the degree from Harvard. [1968a, p. 175]

More than one-half century later, Du Bois noted that the Berlin teachers gave him an understanding of the relation of politics and economics and the connection between European development, America's race problem, and the problems of Africa and Asia (1968a, p. 163).

II. Du Bois' Contributions to Political Economy

Upon returning to America, Du Bois completed his dissertation that became the first volume of the Harvard Historical Series (Du Bois, 1896). Additionally, he became that university's first African-American doctoral graduate.³ Three years later, he published *The Philadelphia Negro* (1873/1899) that many consider to be his finest scholarly achievement.

Between 1898 and 1906, Du Bois conducted five agricultural studies for the U.S.

²The paper, "The Plantation and Peasant Proprietorship System of Agriculture in the Southern United States," was the first of a series of studies on southern agriculture conducted by Du Bois.

³His degree was awarded in history, but his dissertation and studies were supervised by the departments of History and Political Economy.

Bureau of Labor that clearly exhibit the influence of the Historical School.⁴ Some of his other publications in political economy during this period include a paper prepared for the American Economic Association and one solicited by Max Weber for the journal he edited (see Du Bois, 1906a, b).

Unfortunately, the study that Du Bois considers to be his most significant was destroyed by the Bureau of Labor. He recounts that the report was finished by hand with no copy and rushed to Washington where he was told that it would not be published because it "touched on political matters.... I went back to them again to ask if they would allow me to have the manuscript since they were not going to use it. They told me it had been destroyed!" (1968a, p. 227).

Between 1897 and 1910, Du Bois accepted an appointment as Professor of History and Political Economy at Atlanta University. During this period, he initiated an ambitious research agenda for the study of black life. Its success, however, was contingent upon adequate financial support and the cooperation of several leading majority institutions. With adequate support, he argued, this effort would culminate in one of the greatest scholarly endeavors ever undertaken. But the support never materialized. Still, he edited sixteen volumes of research on black life (1968b).

III. The Historical Method

Du Bois' research in political economy is clearly influenced by the historical method. This method rejects abstract theoretical analyses and argues instead that economic life must be studied concretely. Truth, Schmoller proclaims, is only revealed through detailed historical analysis of descriptive material supplemented by a variety

⁴Included among these publications are "The Negro of Farmville Virginia" (1898), "The Negro in the Black Belt" (1899), "The Negro Landholder in Georgia" (1901), and "The Negro Farmer" (1906). (They are collected in Aptheker, 1980.)

of statistical investigations (Karl Pribram, 1983). The method also emphasized the interdependence of economics and other aspects of social life.

The Historical School repudiated Classical Economics on the premise that it erred in making excessive deductions from erroneous empirical facts. While occasionally admitting that economic laws exist, historicists argued that the most effective means of uncovering them is through historical inquiry. Economists must have a "hunger for facts," they asserted, and a willingness to examine the general body of history in great detail. Only then can they derive patterns, processes and generalizations.

Not surprisingly, economic theory suffered under the influence of the historicists. In fact, Schumpeter calls this school's theory "pedestrian." But he credits it with producing unrivaled historical studies that caused a tremendous advance in the accuracy and knowledge of social processes.

Finally, the historicists were extremely active in social reform movements. Yet their scientific credo criticized the injection of value judgments into research. "There was respect for the economic fact," Schumpeter asserts, "and the will to let it speak for itself" (1954, p. 811).

IV. The Historical School's Influence on Du Bois

The extent of descriptive and statistical detail in Du Bois' studies is rarely matched even today. Further, the lack of emphasis on theory strongly resembles the historical method. Speaking of the *Philadelphia Negro*, he asserts, "Of the theory back of the plan of this study of Negroes I neither knew nor cared. I saw only here a chance to study a historical group of black folk and to show exactly what their place was in the community" (1968a, p. 197).

Du Bois' approach matched the Historical School's in two other respects. First, he always studied economic events in the context of their surrounding social phenomena. Second, he never injected normative judgments into scholarly research. Although he was a social activist throughout his life, he

confined his propaganda for racial equality to journalistic editorials and speeches.

Like other economists of the Historical School, Du Bois objected to abstractions and normative judgments in scholarly research. "We simply collect the facts" he once observed, "others may use them as they will." His only predilections were: 1) that African-Americans are part of the human race and have the same endowment and capacity for culture and development as all others; and 2) that African-Americans are deserving of as much scientific investigation as are all other ethnic groups.

V. Du Bois, a Little-Known Economist

Today, if an economist is asked to identify the definitive study of black life, he will inevitably answer Gunnar Myrdal's *American Dilemma*. Yet Myrdal has stated that this status belongs to Du Bois' *The Philadelphia Negro*. If this is the case, then why is Du Bois so unfamiliar to most economists? I close with a consideration of this issue.

Du Bois' contribution to political economy is partly obscured by the historical method that influenced it. The Historical School withered under the assault of the Marginalist Revolution and, by 1910, its method was relegated to economic historians and sociologists. Accompanying its demise, the study of economics became increasingly theoretical and more isolated from other social sciences.

During this same period, Du Bois turned his attention more and more to the study of sociology, a discipline that separated formally from the American Economic Association in 1905.⁵ These occurrences serve to distance his scholarly research from mainstream economics. They also help explain why so few economists are aware of his contributions in political economy. Today,

⁵The research of Max Weber, one of Du Bois' former instructors, also moved in this same direction and today he is noted more as a sociologist than an economist.

his publications are not thought of as economic research. But, at the turn of the century, they were contributions to mainstream historical economics.

There is a second and perhaps more important circumstance that obscures Du Bois' contribution to political economy. Although his research was recognized internationally, as an African-American he was never offered an appointment at a predominantly white university. Confined by race to teach at historically black colleges, he still appealed to the leading academies to conduct research on black life jointly with him. But his appeals were rejected. He notes that the only post he was ever offered at a major white university was a one-year position in the "unusual status of 'assistant' Instructor" (1968a, p. 194).

The constraints that racial inequality imposed upon his research were aggravated further by his famous political debate with Booker T. Washington. Unfortunately, the latter's political influence with white benefactors of Atlanta University led to Du Bois' resignation in 1910. Thus, his most fertile period of scholarly productivity ended and he embarked upon a career of social activism.

Disenchanted with racism and capitalism and falsely accused of being an agent of a foreign government by the McCarthy inquisitions of the 1950's, Du Bois went into self-imposed exile in Ghana in 1961. Two years later, he died while directing the *Encyclopedia Africana* project.

Missed Opportunity: Sadie Tanner Mossell Alexander and the Economics Profession

By JULIANNE MALVEAUX*

Sadie Tanner Mossell Alexander (1898–1989) was the first black woman in the United States to receive a Ph.D. (Thomas Potterfield, 1990). She earned her degree in economics from the University of Pennsylvania in 1921. Her dissertation, “The Standard of Living Among One Hundred Negro Migrant Families in Philadelphia,” was, in her words “an attempt to arrive at conclusions concerning the migrants to Philadelphia, through an intensive analysis of the budgets of a small number of their group” (Mossell, 1921). When she finished her graduate work in 1921, Mossell was unable to find employment in the economics profession in Philadelphia or in the surrounding areas (Potterfield). This is not surprising, since the only academic employment available to African-Americans in the early 1920’s was available at the black colleges, and black women faced barriers to employment at some of those colleges.

In any case, Mossell worked as an assistant actuary at the black-owned North Carolina Mutual Life Insurance Company from 1921 to 1923. She returned to Philadelphia to marry Raymond Alexander in 1923, and entered the University of Pennsylvania Law School in 1924. She was the first African-American woman to graduate from Penn’s Law Schools in 1927, and the first black woman admitted to the Pennsylvania bar in the same year (Potterfield).

Given her family background, Alexander’s academic and career achievements are not surprising. Her grandfather was a bishop in the African Methodist Episcopal Church. Her uncle, Henry O. Tanner, was a noted artist. Nontraditional occupations and employment were not unusual for the Tanner women—an aunt, Hallie Tanner Johnson,

was a physician and founder of the nurse’s school and hospital at Tuskegee Institute (Potterfield).

During her career, Alexander distinguished herself as a lawyer in both the public and private sectors, working as Assistant City Solicitor in the City of Philadelphia in 1928–30 and 1930–34, and serving as a Truman appointee to the Committee on Human Rights (Gerald Fraser, 1989), a Kennedy appointee to the Lawyer’s Committee on Civil Rights, and the Carter-appointed Chair of the White House Conference on Aging (Fraser). She was also active in civic affairs, serving as the Secretary of the National Urban League for 25 years, and as a member of the National Advisory Council of the American Civil Liberties Union. She was the first national president of Delta Sigma Theta Sorority (currently the largest black woman’s public service organization; see Paula Giddings, 1988), and its legal advisor for 35 years.

Alexander’s household seems similar to the modern two-career household. Her husband was a lawyer, a member of the Philadelphia City Council (1951–59), and a distinguished jurist on the Philadelphia Court of Common Pleas. They had two daughters, Mary Elizabeth Alexander Brown (born 1934) and Rae Pace Alexander-Minter (born 1936). Alexander successfully juggled household, family, career, and civic responsibilities. The achievements of her life touch areas that range from the law, government, civil rights, education, aging, and women’s rights (Potterfield).

A striking aspect of Alexander’s career was the longevity of her interest in the topics she identified as important—serving as Secretary of the Urban League for 25 years, and as the Legal Advisor to Delta Sigma Theta for 35 years. Her involvement in the economics profession, on the other hand, seems fleeting. Alexander earned a Ph.D. degree, sought employment in economics

*Visiting faculty, Afro-American Studies Department, UC-Berkeley, CA 94720.

but did not find it, and worked as an actuary for a short time before pursuing legal studies. The Alexander papers suggest that Alexander all but abandoned the economics profession after 1923,¹ although at least one of the books in the Alexander collection suggests that 30 years after obtaining the Ph.D., she maintained at least a passing interest in economic issues.²

Why did Alexander abandon economics? According to her daughter, Rae Alexander-Minter, "there was no way for her to make a living in the profession." Alexander-Minter indicates that her mother did not look back and expressed no regrets about her career, but worked hard at her law practice and at maintaining her family. Indeed, at her peak, Alexander had one of the largest divorce practices in Philadelphia.³

While her withdrawal from the economics profession may not have been a personal tragedy for Alexander, the fact that she did not continue her work in economics seems a missed opportunity for her, for the economics profession, and for the body of economic knowledge that pertains to African-Americans. My goal in this essay is to probe the nature of that missed opportunity, both through discussion of the major example of her economics work, the doctoral dissertation, and through speculation about ways she may have followed up on the dissertation, given her interests.

I. Black Migration and Consumption in Philadelphia, 1916-18

According to Philip Foner and Ronald Lewis (1989), the "machinery of segregation" had been installed in the South by the beginning of the twentieth century. "Economic intimidation, violence, and lynching"

suggested to blacks that the South had no future for them. In addition, the early twentieth century was an economically devastating period in the South, with agriculture plagued by flooding, an epidemic of boll weevils, and other hardships. As the South declined, the North and Middle West developed industrially, especially with demand stimulated by the production needs of World War I. As white men went to war, black men moved North to replace them in industry. "The Great Migration," a significant exodus of black workers from the South, took place in the second decade of the twentieth century, triggered both by hardship in the South and by new opportunities in the North.

Between 1890 and 1915 in Chicago, for example, the black population grew from less than 15,000 to more than 50,000 (Allan Spear, 1967). Similar population jumps took place in other industrial centers, including Philadelphia. Alexander's dissertation, "The Standard of Living of Negro Families in Philadelphia" (henceforth referred to as NMF), looks in detail at this migration in Philadelphia, both from a macro and a micro perspective.

Alexander documents the labor shortage in Philadelphia, and discussed industrial efforts to attract black workers to manufacturing sites. NMF discusses the living conditions for migrant families, conditions Alexander describes as deplorable. She goes on to detail the civic response to poor housing conditions, on the part of the black church, the black middle class, and whites. Some of the racial conflicts that took place because of migration are detailed by Alexander, mainly to place the issue of migration into a sociopolitical context, and to develop research questions and pose hypotheses for her dissertation.

"Was the migrant to Philadelphia able to adapt himself to the environment of an industrial economy?" she asks. "Did his presence help or hinder the racial condition of the city?" Alexander asserts that the standard of living maintained by a people is an index of the extent to which they have adapted themselves to a given environment. She proposes to analyze the incomes and expenditures of a group of migrant families

¹Telephone conversation between Mark Lloyd, Director of University of Pennsylvania Archives and Records center and myself, September 21, 1990.

²According to Potterfield (p. 229): Among the 22 miscellaneous books included in the joint papers of Raymond Pace Alexander and Sadie T. M. Alexander was *Away From Freedom: The Revolt of the College Economists*, edited by Orval Watts in 1952.

³Personal interview with Rae Alexander-Minter, December 10, 1990.

to measure standards of living and "judge the degree of adaptation."

Thus, Alexander set the tone for doing a cross-sectional consumption survey of black migrant families. Over a 2-month period, Alexander visited 100 families in Philadelphia's twenty-ninth ward. Using a detailed questionnaire, she asked about origin, family structure, labor market status, unemployment, and household expenses, including rent, utilities, church, insurance, tobacco, alcohol, carfare, and savings. In a manner reminiscent of contemporary dissertations, Alexander discusses both her research methodology and the accuracy of her data before analyzing results.

The results of Alexander's dissertation provide fascinating information about expenditure patterns, and also reveal her familiarity with federal and municipal data on household incomes and consumption patterns, and theories of consumption and spending. NMF also reveals Alexander's penchant for detail and accuracy, as well as a good eye for reporting of the minute aspects of migrant lives. Discussing expenditures on heat, for example, Alexander expanded the discussion to deal with families who rented rooms where landlords provided heat and ventilation and health aspects of these rentals. She concluded that many of these dwellings "were unfit for families."

NMF reports many of the economic inefficiencies that migrant families were forced to endure. "The average price paid for renting one room was \$163 per year, \$6.05 less than average price of renting a house of four rooms," writes Alexander. She adds that renting a home increased income earning potential since so many renters took in lodgers. Noticeably absent from this discussion, however, was an acknowledgement of the institutional forces that forced black migrant families into inefficient economic arrangements.

Alexander's discussion of migrant spending provided information about the culture and lifestyles of black migrants. She details information about health and the use of free clinics, the financial ties among extended families, and savings patterns, including participation in benevolent societies and church thrift clubs. Alexander con-

cludes the discussion of expenditures by comparing black migrant expenditure patterns with those posited by consumption theorists and those measured by the war labor board. Essentially, she found that black migrant families behaved in the same way Engel theorized they would. The percentage of income spent on food fell as income increased. The percentage of income spent on clothing stayed the same with increasing income. The percentage of income spent on sundries increased as income increased. In a result that differed from Engel's theory, expenditures on rent, fuel, and light decreased as income rose.

After analyzing black migrant budgets and expenditures, Alexander developed a suggested budget. In the context of this discussion, especially as it relates to housing, she dealt with supply and segregation issues and indicated that "a two story brick house, fitted with tub, washstand, and toilet" might be scarce for blacks because "the Negro population of Philadelphia increased without an equal increase in housing." Alexander put off issues of housing availability for the concluding chapter of her dissertation.

Armed with data about actual and suggested spending, Alexander asks two questions. "Do black migrant families earn enough to have fair standards of living, as defined by published reports?" "Do black migrant families choose to spend their money in ways to attain a fair standard of living?" She notes that 64 percent of all families had a sufficient income to provide a fair standard of living, though the primary breadwinner's earnings were enough to provide a fair standard in only 41 percent of cases. She further indicates that some of the families able to afford a fair standard of living do not attain such standards because of "unwise" spending.

In this context, Alexander deals with issues of class and migration in distinguishing segments of the black community from each other. She notes that family size, "ignorance resulting from unwise spending" (insurance spending is especially targeted here), and racial prejudice were all factors preventing black migrant families from attaining a fair standard of living. She deals with both institutional barriers to fair living standards

("Recreation appeared seldom in his budget, for the Negro was admitted to few places where it was offered"); and individual barriers (such as lack of education). Alexander concludes by suggesting that the status of the black migrant can be improving by the "Negro businessman," the black church, and the city, which she says "has the responsibility of seeing that at least adequate housing is secured."

II. Missed Opportunity: Beyond Negro Migrant Families

Alexander's doctoral dissertation illustrates the perception, sensitivity, racial concern, and ability of a young upper middle-class black woman to use her professional skills to tackle a contemporary racial issue. Her dissertation is a case study that reveals institutional aspects of racial segregation in Philadelphia, as well as confirms the consumption theories of the time. It also reveals Alexander's middle-class biases, for example, in her use of terms like "unwise purchases" and her remark that she does not advocate the consumption of alcohol, Prohibition or not. On the other hand, in her concluding chapter Alexander reveals herself both as an advocate for black self-help ("churches could help to alleviate the housing problem by building houses instead of expensive church edifices") and as an advocate of government economic involvement in the housing market.

In thinking of the missed opportunity revealed by Alexander's dissertation, I think about the work that Abram Harris did on black business development, Oliver Cox's work on class, the W.E.B. DuBois Atlanta University studies, and D. Parke Gibson's books on black consumer patterns. Given her interest and ability, Alexander might have followed in any of those directions or, indeed, continued to look at black family and migration patterns both through further case studies and from a macroeconomic perspective. Because Alexander discussed so many possible areas for further research in her dissertation, one can posit that, given the opportunity, she would have had a productive and significant research career.

Indeed, it is possible to speculate that had Alexander pursued her research interests, given her long involvement with the Urban League, we might have seen the earlier production of titles like "The State of Black America," which was first produced in 1975 (John Jacob, 1991). And, given the opportunity to teach, what kinds of students might Alexander have nurtured, and how many other economists would have tackled socioeconomic issues of migration, consumption, housing availability, health care access, and insurance availability?

Alexander's dissertation suggests that the young economist might have taken quite a different career path after she earned her Ph.D. had there only been opportunities for her in her profession of first choice. While the economics profession's loss was the legal profession's gain, Alexander might well have made a significant contribution to economics, given the opportunity.

The Rise and Fall of Negro Economics: The Economic Thought of George Edmund Haynes

By JAMES B. STEWART*

This analysis examines the treatment of economic issues in studies by George Edmund Haynes. Born in 1880, Haynes became one of the first African-Americans to earn a Ph.D. in sociology. He was awarded the doctorate by Columbia in 1910 after earlier periods of study at Fisk, Yale, and the University of Chicago. Haynes' formal connection with the economics profession derives in part from his tenure as Director of Negro Economics for the U.S. Department of Labor during World War I. That appointment resulted primarily from the visibility of Haynes' work with the Urban League.

Haynes was serving as the League's Educational Secretary and was Professor of Social Science at Fisk University at the time of his selection for the Negro Economics directorship. Earlier he had completed an investigation of the adjustment of black migrants to New York as well as a general study of the condition of blacks in cities (see his 1912, 1913 articles). Coincident with his tenure as Director of Negro Economics, his case study of the adaptation of black migrants in Detroit was published in 1918.

Haynes' appointment to a position labelled "Director of Negro Economics" was somewhat paradoxical. The paradox derives from the underlying theme of his work, namely similarities in the effects of economic and social forces on blacks and whites. This focus led to the understatement of the role of discrimination in creating barriers to the achievement of equality of condition.

Many of Haynes' perspectives anticipated contemporary economic approaches to the study of social problems. Although he lacked

access to modern economic categories, the contemporary labels appropriate for characterizing the foci of Haynes' research include the economics of rural-urban migration, the structure and functioning of urban labor markets, economic discrimination, and the underground economy. Haynes approached these areas with the eye of a social change agent rather than as a theoretician. But despite this practical problem-solving orientation, his investigations were undergirded by economic models of individual behavior that should be familiar to modern economists.

The similarities between Haynes' perspectives on the economic circumstances of African-Americans and much contemporary scholarship underscore the usefulness of a detailed examination of his approaches to the study of each of the subject areas mentioned previously.

I. The Economics of Migration

Haynes (1918) employed a general push-pull model to analyze forces contributing to the northern migration of blacks in the early twentieth century. For Haynes, "The cause first in importance...is economic" (p. 6). He argued that between 1914 and 1918, the districts that had "the worst economic conditions to face...have lost the largest numbers of their Negro population" (p. 6). He argued that an extraordinary demand for labor had been created by World War I and labor shortages were exacerbated by the disruption of European emigration. As a result, northern employers discovered "the unworked Negro labor supply of the South" (p. 6).

Haynes suggested that the size of the black migration was in part the result of a "money illusion." In his words, blacks were "thinking in terms of money wages not real wages" (1918, p. 7). This money illusion was

*Department of Labor Studies and Industrial Relations, Pennsylvania State University, University Park, PA 16802.

promulgated by tales of high wages told by northern labor agents. He also noted the use of free transportation as an incentive to migrate.

Although Haynes saw economic incentives as paramount, the "social causes of migration" were also described. These included poor housing, poor schools, Jim Crow segregation, disfranchisement, discrimination in the criminal justice system, and mob violence. Haynes also discussed the role of public policy in determining the configuration of the opportunity set of potential migrants. Different public thrusts in the North and South had made the North a relatively more attractive region of residence. In the North, public education and public goods such as parks and recreational centers were identified as important initiatives. In the South, public efforts to stem the exodus of blacks through regulation of northern labor agents and tightening debt peonage provisions were highlighted as indicators of increased levels of oppression.

Haynes maintained that his model of migration could be applied to other periods and to other population groups. The post-1910 migration was for him, "only the third swell in a movement...which ha[d] been in progress since 1860" (1918, p. 6). In the New York study he asserted that, "the general movement of the Negroes...does not seem to have been very different from that of whites" (1912, p. 14). In fact, the movement of the white and black populations towards cities was hypothesized to be coincidental.

The obvious implication of the view that underlying causes of migration were similar across populations was that "the problems which grow out of his [blacks] maladjustment to the new urban environment are solvable by methods similar to those that help other elements of the population" (Haynes, 1912, p. 14).

II. The Structure and Functioning of Urban Labor Markets

In modern parlance, Haynes employed a segmented labor market model to analyze the structure and functioning of urban labor

markets. The primary sector consisted of jobs in the industrial sector while the secondary sector was dominated by service occupations. Changes in aggregate demand and variation in labor market conditions were treated as potential sources of reductions in inequalities generated by segmentation.

In the New York City study, Haynes found that most blacks were employed in domestic and personal service occupations (1912, p. 77). However, for Detroit, he observed a much wider range of employment of African-Americans (1918, p. 15). One of the obvious sources of the differences was the demand for labor created by World War I. In fact, Haynes observed that previously blacks in Detroit had been "confined to some of the domestic and personal service occupations [and h]e was probably losing ground in these until the industrial demand of the Great War came" (1918, p. 12).

The effects of blacks' relegation to the secondary sector was viewed as producing a cycle of diminished economic well-being such that "there is a larger number of competitors within a limited field with a consequent tendency to lower an already low wage scale. In this way the limitations of occupational mobility react upon income, producing a low standard of living, the lodger evil, and social consequences..." (Haynes, 1912, p. 77).

Haynes was especially concerned about mothers of young children in the labor market and crime. On the issue of crime he observed, "Arrests and prison commitments have many factors which figures do not show and are quite as much a commentary upon the white communities at large as upon the unfortunate Negro law breakers" (1912, p. 39). The "lodger evil" was the practice of renting rooms in the home to supplement family income. Haynes concluded that many women had to "help earn the daily bread of the family" and that "Their low income power forces these families to the necessity of completing the rent by means of lodgers, deprives the children of mothers' care, keeps the standard of living at a minimum, and thus makes the family unable to protect itself from both physical and moral disease"

(1912, p. 89). Haynes found that in New York approximately half of the households included lodgers.

Three factors were hypothesized by Haynes to account for the relegation of blacks to the secondary sector: (a) "historical conditions of servitude"; (b) "a prejudice on the part of white workmen and employers"; and (c) "inefficiency of Negro wage-earners for competition in occupations requiring a higher order of training and skill" (1912, p. 77). Most of Haynes' attention was focused on the "inefficiency" problem despite his observation that the age distribution of black workers in New York City suggested that "They are either killed off by the conditions under which they work and live, or drift away from the city at a premature old age" (1912, p. 57).

Haynes seemed to take at face value Detroit employers' assertion that many black workers did not work fast enough and were "disinclined to work out-of-doors when the cold weather comes" (1918, pp. 17-18). He recommended that the churches "provide lectures, social study classes to overcome these faults" (p. 20). This instruction was to include "instruction in how to dress and in simple repeated assurances that [workers] need not fear freezing to death if they are properly clad" (p. 20). Haynes also proposed training programs for domestic workers as a major initiative. This proposal was curious because, he had argued elsewhere that "the large majority of Negroes in domestic and personal service are capable, temperate, and honest, and remain with one employer a reasonable time..." (1912, p. 89).

Haynes saw investments in human capital as critical both for gaining access to occupations opened up by labor shortages and for retaining those jobs. His recommended interventions emphasized broad involvement of voluntary organizations like the Urban League and churches to change the characteristics of workers. He focused little attention on exploring ways to reduce segmentation. One of his most fascinating discussions of this issue was associated with an experiment involving a pants manufacturing plant employing only black women (excluding

management). Haynes saw this experiment as contributing to black workers gaining a permanent hold in Detroit industries (1918, p. 19). Contemporary perspectives would, of course, contest this assessment. To understand Haynes' views requires discussion of his theory of economic discrimination.

III. The Economics of Discrimination

Haynes' limited discussions of discrimination are carefully worded and strategically located in the various analyses. It is the very last statement in the New York City study where the declaration appears that "Negro wage-earners and business men have great difficulty in scaling the walls of inefficiency and of race prejudice in order to escape the discomforts and dangers of a low standard of living" (1912, p. 148).

The principal theory of discrimination employed by Haynes was a forerunner to modern statistical theories of discrimination. He argued that one of the consequences of the large-scale migration of unskilled blacks to urban areas was an increase in residential segregation. This segregation limited the contact between blacks and whites leading to the assessment of the capabilities of individuals on the basis of ascribed group characteristics. In Haynes' words,

[T]oo much of the white man's knowledge of the Negro people is derived...from domestic servants and from superficial observation of the loafers about the streets. The best elements of both races, thus entirely removed from friendly contact, except for the chance meeting in the marketplace, know hardly anything of their common life and tend to become more suspicious and hostile toward each other than toward strangers from a far country. [1913, pp. 110-11]

Haynes maintained that "prejudice, when displayed by employers, is partly due to inefficiency...and the failure to discriminate between the efficient individual and this untrained throng" (1913, p. 112).

Haynes also allowed, however, that in some cases white employers and employees simply had a Becker-type "taste to discriminate," that is, "in the cases of many employers and employees...the opposition to the Negro in industrial pursuits is due to a whimsical dislike of any workman who is not white and especially of one who is black!" (1913, pp. 112-13). The statistical model of discrimination was used to assign blame to the victim for fueling discriminatory sentiments while the Becker-type model mildly chastised the discriminator. On balance his recommendations placed the principal burden of adjustment on the victim. He proposed that whites accord blacks equal justice via "a square deal in industry, in education, and in other parts of the common life" (1913, p. 118). However, his first recommendation was as "an organized effort to acquaint the Negro in the country with the desirability of remaining where he is unless by education and training he is prepared to meet the exactions of adjustment to city life" (1913, pp. 118-19). Thus for Haynes, it was better for blacks to remain in the shadow of the plantation than to risk aggravating aggregate adjustment problems in the North.

IV. Conclusion

We can only speculate as to what recommendations Haynes would have for residents in contemporary urban environments who cannot "meet the exactions of adjustment to city life." However, constructions similar to those of Haynes can be found in many contemporary neoconservative analyses (Thomas Sowell, 1981; Walter Williams, 1982). Neoconservative analysts tend, however, to employ much less sophisticated analytical frameworks than Haynes.

Haynes applied his basic approach to other issues of contemporary interest including black business enterprises (1912). His study of the involvement of adolescents

in junk dealing could be applied easily to examine the contemporary underground economy (Harry Grigg and Haynes, 1919). Haynes discussion (1950) of Africa as the continent of the future extended the application of many of his models to the international arena. "In the field of social values," he wrote, "the Africans hold still to kinship and family ties and communal interdependence that may offer valuable patterns to a world writhing in rugged individualism" (p. 20). Haynes offered a scenario that may have important implications for the next century; "European and American workers may well ponder what will happen when factories...begin to ship their products made with cheaper wages and raw materials, to the world markets in vessels built in African shipyards" (1950, pp. 20-21).

Celestial Mechanics and the Location Theory of William H. Dean, Jr., 1930–52

By JULIAN ELLISON*

William Henry Dean, Jr. was born in 1910 and died in 1952. He was the only son, and third of four children, of Reverend William Henry Dean and the former Ella Cornelia Green. His father was a Methodist minister, and the family lived in the cities in which he pastored churches: Lynchburg, VA; Washington, D.C.; Baltimore, MD; and Pittsburgh, PA. The son graduated from Frederick Douglass High School in Baltimore in 1926 as valedictorian of his class. He attended Bowdoin College in Maine, graduating summa cum laude in 1930. He then entered Harvard University, where he earned the M.A. and the Ph.D. in economics in 1932 and 1938, respectively. His subsequent career included stays with Atlanta University, 1933–42; City College of New York, summer 1939; U.S. National Resources Planning Board, 1940–42; U.S. Office of Price Administration, Virgin Islands, 1942–44; National Urban League, 1944–46; and United Nations, 1946–52 (Rayford Logan and Michael Winston, 1982).

This paper examines briefly the sources of location theory in the mathematics and astronomy of the day, and Dean's application of results from these fields to economic location theory in his doctoral dissertation at Harvard University in 1938.

I. The Development of Economic Location Theory Before Dean

A line of influence stretching from Joseph-Louis Lagrange (1772) to Georg A. Pick (Weber, 1929) to George D. Birkhoff (1915) to Halford J. Mackinder (1902) to

Dean (1938) accounts for the peculiar contours of Dean's economic location theory. These names represent simply the peaks observable from the present on an azimuth from Dean to the initial modern application of geometry to celestial space. It should not be presumed, and is here expressly disclaimed, that this is an exhaustive account of the process of development involved in the Dean accomplishment. In particular, only allusions are made to the very important roles played by city and regional planning, geography, international trade theory, and by the *Quarterly Journal of Economics* and the *Review of Economic Statistics* in the creation of Harvard location theory (Sidney McCluskey, 1963; Erwin Finlay-Freundlich, 1958; Otto Dziobek, 1962; Victor Szbeheley, 1967; Eric Bell, 1965; Birkhoff).

II. Dean's Doctoral Dissertation and Its Contribution to Location Theory

Dean's entire original dissertation was comprised of 8 chapters divided into two parts: Part I, "Pure Theory of Industrial Location," consisted of the first 3 chapters; Part II was entitled "Location in the Geographic and Historical Environment," and contained the remaining chapters. His published book in 1938 contained Part I and chapter 5.

The idea of a plane triangle or polygon as the representation of the industrial location problem was taken from the restricted problem of three bodies in celestial mechanics. Dean's book contained three sections illustrating the relationship of location theory to celestial mechanics. In chapter 2, "The Regional Pattern: Static Theory of Industrial Location," he constructed a locational triangle and a weight triangle, that were interpreted as showing the relationships among sites of input sources, production, and market. Each of these sites represented mass. Their positions were determined by analogy

*Mid-Atlantic Research Corporation, 9318 Grazing Terrace, Gaithersburg, MD 20879. A complete list of references for all articles and books cited herein may be obtained from the author upon request.

to the laws of gravity and celestial motion of Isaac Newton (1946), Lagrange, Poincaré (1957, 1905–10, 1912), and Birkhoff, and in particular by analogy to the restricted problem of three bodies.

In his article, Birkhoff presented a geometrical diagram representing the restricted problem. The diagram showed an isosceles triangle superimposed on a rectangular coordinate system, with the vertices of the triangle representing the points of mass of the three bodies, and the sides representing the motion vectors. Dean used a virtually identical diagram to illustrate the locational triangle.

In chapter 3, "The Regional Pattern: Dynamic Strategy of Industrial Location," Dean alluded to a second great force of nature, electromagnetism, in formulating his theory of location. Dean here followed James Jeans (1908) in his analysis of electricity, and identified electrical power as one of the two major technical determinants of location, along with surplus food.

In chapter 5, "Nodality and Commercial Agglomeration. Selections," Dean returned to astronomy to find the concept of a node, or the intersection of the orbits of celestial bodies. The node concept had been applied to geography by Mackinder, who considered that nodes in human geography had positive consequences. Dean, indeed, argued that geographical nodes, or intersections of human trade routes, are likely solution sites for the location of industrial production facilities. Moreover, since such nodes develop at topographically suitable sites, Dean here abandoned the featureless plain preferred by Carl Launhardt (1872), Alfred Weber/Georg Pick, Frank Fetter (1924, 1931), Harold Hotelling (1929), and Edgar Hoover (1937) as the environment of their location theories, and moved in a more "realistic" direction.

Dean's most important contribution, therefore, was to apply the mathematical models and methods of analysis of celestial mechanics to the solution of spatial problems in economic analysis, with explicit references to published sources. In particular, he utilized the two special solutions of the restricted problem of three bodies found by Lagrange in 1772, an equilateral triangle

model and a straight line model, although he did not develop his discussion of the latter. Hotelling had used the linear model earlier, but had not revealed its origins. Neither had Edward Chamberlin (1962) in his critique of Hotelling; nor had Hoover. Following Pick, Dean showed that Hotelling's line model was a special case of the polygon model. As the sum of the interior angles of the locational polygon approached 0° or 180° , the polygon reduced to a line. The possibility of reducing a triangle to a line also is alluded to in Dzibek's book on planetary motions, and in Jeans' article (1954) on harmonic analysis.

Pick, born in Vienna, was ordinary professor of mathematics at the German University of Prague from 1892 to 1929. From 1929 to 1938, he served as rector of the University of Vienna. Thus, while Weber was at Prague from 1904 to 1907, they were colleagues, and in 1909 became collaborators on the economic theory of location.

Dean (p. 22) also found that by using the methods of the astronomers, he could conclude that 1) the parallelogram of forces theorem permitted the solution to the production location problem in spatial economic theory to be found at an interior site in the locational triangle, rather than at one of the vertices or along one of the sides, and 2) polygons with any number of vertices could be analyzed in the same way to solve an economic location problem.

Interestingly, using the parallelogram of forces to find the interior solution site as Dean did produces a diagram of a pyramid.

Dean's source for the conclusion that any polygon could be used for this purpose was not Launhardt or Weber/Pick, but Lynn Loomis, a Harvard graduate student in mathematics in 1938, who from 1941 to 1982 would be a faculty member in the Harvard Mathematics Department. Loomis was following the precepts of Birkhoff, Julian Coolidge and William Graustein, his professors in mathematics at Harvard. Dean's solution thus owed more to their topological bias than did those of Launhardt and Weber/Pick.

In 1953, Loomis published a book on harmonic analysis, a technique for analyzing periodic phenomena, which developed from

Pythagoras and his mathematical analysis of music, especially the problem of the vibrating string. This type of analysis has had a great significance in the search for the solution to the three body problem in the twentieth century, and in particular analyzes nodes. Poincaré and Birkhoff were especially notable contributors to this work. (Also see Yitzhak Katznelson, 1969; Jeans, 1954; Loomis, 1953; Marston Morse; Birkhoff; Weber; "Pick," 1959.)

Dean acknowledged the work of recently published location theorists, but stated that he had not altered his book to take into account their findings. It appears from his citations of economics faculty members under whom he studied, that agricultural economist John Black (1926) and economic historian Abbott Usher (1929, 1936) had the greatest impact on Dean's thought.

Dean's analysis clearly anticipated, and thus can be seen as the objective source of, the gravity or potential models in location theory developed beginning in the late 1940's by John Stewart (1948) and others.

(See Jeans, 1905; Scheffers, 1900; 1904; Walter Isard, 1960; George Zipf, 1946.)

Dean's analysis was in accord with the profession's experiment with analogies from physical science and mathematics in the 1920's and 1930's to find an objective way to analyze resource allocation choices. Thus, he was at the forefront of the experimentation in analytic technique in economics at that time.

The significance of Dean's approach can be gauged by reference to the work of fellow Harvard graduate student Paul Samuelson during this period. In 1947, Samuelson extended the use of the location theorist's mathematical and scientific sources to economics more generally, and made these methods central to conventional modern economic analysis, using several Birkhoff works. In the period prior to 1950, Samuelson is the only economist besides Dean to cite or otherwise explicitly refer to the work of the Harvard mathematicians and astronomers in celestial mechanics, and to use their results in his own work.

POST-COMMUNIST ECONOMIC TRANSFORMATION: HUNGARY VS. POLAND[†]

Institutional Legacies and the Economic, Social, and Political Environment for Transition in Hungary and Poland

By KEITH CRANE*

All the new governments of the former nations of the Warsaw Pact have committed themselves to creating market economies out of the shambles of the old centrally planned systems. On the eve of the revolutions that swept Eastern Europe in 1989, only the governments of Hungary and Poland had successfully altered some of the main features of the Soviet-type model. Because they had already eliminated a number of restrictions on private enterprise, introduced markets in some areas, and attempted to employ a few of the macro-economic instruments used in market economies to regulate economic activity, economic agents in Poland and Hungary have a familiarity with the institutions and functions of market economies lacking in the other countries.

This greater familiarity could lower the costs of transition to a full-fledged market economy. In the process of transition, old ways of doing things (activities or technologies) have to be discarded and new ones learned. New institutions, such as a commercial banking system and capital markets, have to be created. Because many economic agents in Hungary and Poland have already made mistakes that occur in learning how a market economy operates, fewer resources may now need to be expended in learning to adapt to the new market systems. On the other hand, the habits ingrained under the

old, reformed systems may make the transition more difficult. In particular, managers of state-owned enterprises may have become so accustomed to avoiding adapting to the continual perturbations in economic policy characteristic of the reformed Hungarian and Polish systems that they will focus their energies on lobbying to maintain subsidies, rather than seeking to make their operations more efficient. If this should be the case, countries such as Czechoslovakia or Bulgaria which are only now attempting to change their economies may incur lower costs in the transition, because economic agents, especially managers, will be less resistant to change.

This paper speculates on the advantages and disadvantages of past experience in economic reform by analyzing the nature and degree of exposure to markets in Hungary and Poland. Because economic policy changes of the enormity of those taking place in Eastern Europe are not introduced in a vacuum, the paper also discusses the economic, social, and political environment on the eve of the creation of the new, non-Communist governments. It concludes with a discussion of the implications of previous experience with reforms and of the environment in which reforms are introduced for the pace and sequencing of the transition to a market economy.

I. Legacies of Reform

Hungary. The Hungarian government adopted a package of changes in its economic system, the New Economic Mechanism (NEM), in 1968. This package of laws and institutional changes explicitly acknowledged many of the primary failures of the

[†]*Discussants:* Márton Tardos, Hungarian Academy of Sciences; Morris Bornstein, University of Michigan; John P. Hartt, Congressional Research Services.

*PlanEcon, Inc., 1111 14th Street, NW, Washington, D. C. 20005.

Soviet-type system; most notably, the absence of signals that would permit the efficient allocation of resources, the lack of incentives to efficiently utilize inputs, and the inability of the system to exploit potential gains from trade. The NEM attempted to remedy some of these problems by 1) giving enterprise managers' more independence and tying their remuneration to profits; 2) eliminating compulsory plan targets and allocating more resources through markets; 3) loosening price controls on a number of goods; and 4) introducing a single commercial exchange rate for enterprises.

After a period of retrenchment between 1973 and 1978 brought on by domestic economic problems, the deteriorating international economic environment, and political pressures, internally and from the other members of the Warsaw Pact, the government introduced a new round of policy measures in the 1980's designed to make the economy more market oriented (Jan Adam, 1987). The government created a two-tier banking system, restructured the price system so that it more faithfully followed relative prices on world markets, and liberalized foreign trade. The latter was accomplished through the relaxation or elimination of import controls, and by lowering barriers to entry for potential exporters. Beginning in 1982, the government also relaxed restrictions on the size of private enterprises and later permitted the creation of limited liability companies. In general, the climate for private business was much improved.

However, in contrast to the simultaneous introduction of a package of reforms in 1968, many of these measures were introduced separately and often for different goals; at times these measures worked at cross purposes. For example, in order to preserve current jobs for workers, the government expanded subsidies to prevent large, state-owned firms from going bankrupt. Because of pressures on the balance of payments, it frequently clamped on very strict import controls in the hope of narrowing Hungary's current account deficit (Janos Gacs, 1987).

In the year before the installation of the new government in 1990, the socialist government accelerated the pace of change.

The government passed laws permitting the conversion and establishment of joint stock companies, eliminated restrictions on private enterprise and foreign ownership, and liberalized most prices. It also passed laws on the privatization of state-owned property. In many ways the outgoing government took a more radical approach to economic change than has the current government.

Poland. Successive Polish governments made a series of attempts at economic reform (1956, 1972, and 1982). The last attempt has had more staying power than the previous two.

The 1982 reform began inauspiciously. The reform was implemented in January 1982, immediately after the imposition of martial law in December 1981. This reform was much more focused on the question of control than Hungary's NEM (*Kierunki reformy gospodarczej*, 1981). In Hungary, the ministry hired and fired the managing director. In Poland, enterprise councils, freely elected by the work force, were to decide on the directors, vote on corporate strategy, and dispose of the firm's assets. After the imposition of martial law, the government modified the original reform plans to give the ministries more control than the councils. Nonetheless, Polish enterprise managers were more beholden to workers and less beholden to ministries than their Hungarian counterparts (Jan Lipinski and Ursula Wojciechowska, 1987).

The reform shared the emphasis on trade liberalization, some price decontrol and more independence for enterprises of the Hungarian reform. It differed in the lesser role of markets in allocating consumer and intermediate goods, a consequence of misguided attempts to curb inflation through price controls. The Hungarian authorities wielded firmer control over the money supply than did the Polish. Consequently, inflation was lower and the government felt more confident that price liberalization would not degenerate into a more rapid rate of inflation. Thus, markets developed for a number of products in Hungary. The Polish government was much more willing to accept and monetize wage increases. Consequently, it clung to a series of ineffectual instruments, such as price controls,

to combat inflation. These policy instruments made it impossible for markets in intermediate goods and raw materials to develop, thereby preserving the old administrative system of allocating resources.

In contrast to Hungary, the last several months of Communist rule were disastrous in Poland. Although the Communist government established the equality of private and state enterprise and eliminated barriers to entry in most industries, it rapidly accelerated the rate of money creation, partly in an attempt to "buy" the 1989 elections. Inflation soared to year-on-year rates of over 700 percent.

II. The Economic, Social, and Political Environment

Despite previous experience with reforms, the new governments' policies were more directly affected by the economic, social, and political environment that existed upon the transfer of power.

Economic Environment. The new Hungarian government took power after a decade of very slow economic growth under the former Communist regime. The GNP grew at an average annual rate of 1.5 percent between 1980 and 1989. Although a substantial share of the population was able to supplement their incomes with private-sector employment and some entrepreneurs greatly increased their incomes, real wages fell 6.5 percent over this period. Furthermore, a large number of people fell below the official poverty line. To compound matters, inflation began to accelerate towards the end of the decade, reaching 17 percent in 1989.

The only dynamic sector of the economy in the 1980's was the private sector that accounted for all economic growth. Artisans doubled their share in net industrial output. The number of limited liability companies soared from 10,000 in 1988 to 23,000 in the first half of 1990. Newspaper accounts and anecdotal evidence suggest that the sector is considerably larger than indicated by official statistics, possibly as much as 30 percent of GNP (Janos Kornai, 1986). Payments for construction and repair services are usually made in cash and many of the self-

employed do not register with the government in order to avoid taxes.

Polish economic performance under the reform was little better than Hungary's. Productivity measures failed to improve, shortages persisted, and were generally more prevalent than in Hungary. Capital continued to be poorly allocated; rates of return on new investment were very low by international standards. By some measures, foreign trade performance improved. Exports became less concentrated in particular products and grew more rapidly than from other Warsaw Pact countries.

As in Hungary, the private sector in Poland exhibited extremely dynamic growth. Private sector employment in industry rose from 271,000 workers (5.2 percent of the industrial labor force) in 1980 to 717,400 workers (14.7 percent) in 1989. Private-sector output grew at commiserate rates.

Both countries faced severe balance-of-payments problems throughout the decade. After 1980, Poland failed to service its hard currency debts. Debts to commercial banks were eventually rescheduled; however, Poland refused to pay interest on debts to Western governments until Western sanctions were removed. Subsequently, interest on these debts was capitalized and loans rescheduled. However, these policies increased Polish debt from \$27 billion in 1981 to \$39.2 billion in 1989. Hungary remained solvent during this period, but increased its debt from \$10.216 billion in 1982 to \$20.605 billion in 1989. The government's policies were highly ineffectual in controlling the current account deficit.

Reforms failed to accelerate economic growth or improvements in factor productivity in either country in the 1980's. The socialist sector (cooperative and state-owned firms) performed very poorly. Among the many reasons for the failure of the reforms to accelerate economic growth, two stand out. 1) The state never created an effective mechanism to efficiently allocate capital (Gerhard Fink, 1982). It continued to make almost all investment decisions. Political pressures, not prospective rates of return, remained the determinants of capital allocation. 2) Enterprise managers were rewarded for their ability to respond to the

desires of their superiors in the supervising ministries, not on increasing profits, notwithstanding the statements embodied in the reform. Enterprises performed accordingly.

The Social Environment. Public opinion polls register greater concerns about crime in Poland. The decline in fear of the security apparatus and a general loosening of social strictures appears to have been followed by an increase in crime. Greater press freedom has probably resulted in more reportage. The combination led to a greater social concern about personal security.

In both Poland and Hungary, the elderly have been the most harmed by accelerating inflation, although government workers such as teachers and health professionals have also complained bitterly. The governments have not maintained the real incomes of the elderly through indexation.

Many people, particularly low-level bureaucrats and unskilled workers, became increasingly anxious about the possibility of unemployment. The combination of more rapid rates of inflation, the threat of unemployment, higher crime rates, and a general uncertain future has elicited two general reactions in both countries. A substantial share of people grasped the new opportunities, taking pleasure in the decline in regimentation. They have started their own businesses or tried to make the state-owned firms in which they work more competitive. However, another large group has felt more anxious and insecure in the emerging new system. For reasons of age or training, this group sees few prospects in the new system. Although they have not voted for the successors to the former communist parties, they have been fickle voters, seeking those parties which promise them some protection from the new economic uncertainties.

In both countries many indicators point to a decline in the quality of life over the past decade. Life expectancy for males has declined due to diet and higher levels of alcohol and cigarette consumption. Very high levels of air and water pollution have also contributed to lower life expectancies than in Western Europe.

Political Environment Although Poles and Hungarians shared many of the same social

problems and worries, the political environment on the eve of the transition was far different in the two countries. The opposition came to power in Poland after waging a long struggle against the government. It encompassed a strong labor movement and urban intellectuals, and had the general backing of almost the entire country as shown by Solidarity's sweep of the 1989 spring elections. This strong support made it possible for the opposition to take power despite its minority status in Poland's lower house, the Sejm. The opposition was therefore able to put together a list of candidates and a government that contained several well-known names with experience in public speaking and politics.

In contrast, the main Hungarian party, the Hungarian Democratic Forum, was midwived by Imre Pozsgay, one of the four leaders of the Hungarian Socialist Workers' Party. Founded in the fall of 1988, originally the Forum was a loose coalition of intellectuals and people who ascribed to the "populist" tradition in Hungarian intellectual and political thought that focused on the Hungarian peasant and the wellsprings of Hungarian nationality.

Hungary's second largest political party, the Free Democrats, was created by several of the dissidents that had badgered the Hungarian government since the 1970's. It ascribed to the more cosmopolitan, liberal tradition. It has formed an alliance with the Young Democrats, a more radical, outspoken group of young Hungarians that focuses on human rights issues and is strongly pro-market. Thus, in contrast to Poland where the opposition remained united against the communist regime, Hungary approached the changing environment with an incipient system of parties with clear policy differences.

III. Implications and Conclusions

Despite the shortcomings of the reforms, they appear to have given Poland and Hungary a leg up in the process of transformation, in part because some of the institutions necessary for a functioning, modern market economy had already been partially created, because of the greater familiarity of their inhabitants with market systems,

and probably most importantly, because past changes had led to the emergence of a large group of entrepreneurs with experience in opening and operating private businesses. In fact, roughly half of all Hungarians and a large percentage of Poles had worked in a private business or activity before the change of government. Thus, a tradition of working in and opening up private businesses has taken root.

The major negative experience with reform was that economic agents came to expect frequent modifications of government policies and regulations. However, governments of countries with more traditional socialist systems also frequently modified the rules so enterprise managers in all the countries had similar experiences in this regard. They learned that the most remunerative activity was to learn how to evade new regulations or lobby government officials so as to obtain favorable treatment.

The experiences of these countries with reform suggest that it is better to introduce a consistent package of reform measures at one time, rather than sequentially. In most cases all the policy measures are necessary to elicit the appropriate microeconomic responses. They also suggest that the governments need to continue to push institutional changes after the initial policy packages, so that government agencies begin to operate in a way conducive to the development of a market economy as well as the private sec-

tor. Finally, their experiences suggest that the quicker reforms are implemented, the better. Time and again, the Polish and Hungarian governments failed to introduce a measure because of "political" costs, only to introduce the measure later after economic conditions had further deteriorated, because they now felt they had no choice.

Transformation Programs: Content and Sequencing

By FARID DHANJI*

Conventional wisdom will have it that Poland opted for a dramatic, compressed dash towards market capitalism—a “Big Bang” that in one stroke shed central planning and dismantled bureaucratic interference in large areas of economic decision making. Hungary, it is believed, has taken a more gradual, time-consuming, less forced approach towards the same end. These perceived contrasts in strategy (“shock therapy” vs. “gradualism”) are keenly debated in policy reform circles throughout the region, both with respect to necessity as well as to feasibility.

The conventional wisdom greatly simplifies the contrast between the two countries. Recent political developments in Hungary have generated a substantial acceleration of reform efforts. The Hungarian reform program now operates on as broad a front as the Polish program: abandonment of central controls, price liberalization, introduction of competition, privatization, financial and fiscal system modernization, development of social safety nets, legal, regulatory and institutional reform, and so on. It seeks a no less fundamental and far-reaching change.

The perception of gradualism probably has more to do with the past 20 years of Hungarian experimentation with piecemeal modifications to the economic mechanism (Janos Kornai, 1986) than to the present reality. That past experience certainly suggests that without genuine political commitment to a market economy, and particularly to a broad-based system of private property rights, systemic reforms in formerly socialist economies will not succeed.

Once these precepts are accepted, the specific agenda items for reform appear to take on the same character in all reforming

economies. The pace and sequencing of economic and institutional changes are then dictated by initial starting conditions that differ greatly between countries (Stanley Fischer and Alan Gelb, 1990).

Price liberalization and the dismantling of central coordination can be accomplished overnight; the establishment of new legal systems, privatization, the restructuring of enterprises, generating attitudinal and behavioral changes in populations, all perforce take much longer. As a result, it may be expected that the ambit for genuine choices on pace and sequencing on policy and institutional change will narrow over time and that the content of reforms in Hungary and Poland and other countries will increasingly resemble one another.

I. Macro Stabilization, Price, and Trade Liberalization

In essence, the January 1990 Big Bang in Poland was aimed at eliminating the near hyperinflationary conditions in 1989, occasioned by the prior complete breakdown of wage and credit discipline. (See David Lipton and Jeffrey Sachs, 1990, and Dariusz Rosati, 1990, for details.) The uniqueness of the program, however, and its dramatic implicit judgment on the shock therapy vs. gradualism debate, lay in the acknowledgement of the fact that under the new competitive rules of the game, significant unemployment would result from enterprise bankruptcies and redundancies. This was deemed acceptable, and necessary for economic restructuring.

The Big Bang program continued the substantial earlier progress achieved in jettisoning central coordination and liberalizing price setting. About 95 percent of producer and consumer prices are now freely set in Poland (Lipton-Sachs, p. 114). Trade was largely liberalized with very low tariffs set in the course of the year and the zloty was made convertible for most current account transactions.

*World Bank, 1818 H Street, NW, Washington, D.C. 20433. The views expressed in this paper are solely my own, and should not be attributed to the World Bank.

The results of the first few months of the program are now in, and there are some major surprises. On the positive side, first, there has been a practical elimination of shortages; second, the inflation rate has been substantially reduced from its preprogram peak of 50 percent per month, to 3–4 percent per month. On the negative side, measured output (that, unfortunately, neglects the contribution of the private economy) will likely drop 15–20 percent over the year as compared with an anticipated drop of about 5 percent. Unemployment of about 400,000 persons was expected; unemployment is now about 1 million, 7 percent of the labor force, and is expected to climb significantly higher. Real wages have fallen by about 30 percent (although the meaningfulness of this statistic is controversial, as it is measured against a base period when shortages prevailed). A major surprise has been a substantial export boom to convertible currency markets accompanied by a decline in imports; as a result, a trade surplus for the year is expected. A second major surprise has been a surge in enterprise profit margins. No bankruptcies have been observed.

Is this mostly “shock” and little “therapy”? As yet, no clear and plausible analysis has yet emerged—understandable in view of the novelty of the experience. Moreover, distinguishing between the effects of the necessary stabilization program, compounded now by the demise of the CMEA and the recent increase in oil prices, and the effects of the systemic structural reform measures, is virtually impossible empirically. While there is some anecdotal evidence that enterprises are responding creatively to the new market environment, for example, by abandoning unprofitable product lines, or by establishing new distribution outlets (Erika Jorgenson et al., 1990), it will be some time before it is known how pervasive and deep rooted the changes are, and how well enterprises are positioning themselves to deliver a strong supply response in the new market environment. The continuing price increases through the exercise of dominant positions in the face of declining demand must, however, give pause to any

over-sanguine view that a market culture is being systematically embedded in the state enterprise sector. At the same time, the rise of a new, flourishing private sector has been one of the most visible and promising aspects of the reforms.

Meanwhile, dissent is heard that the stabilization measures have comprehensively overshot their objectives (see Gregory Kolodko, 1990; Rosati) leading to urgent calls for domestic reflation. This position has its critics who point to the continued high levels of inflation, and to the considerable evidence that stabilization programs most often fail because they are not sustained. Political support for the program has also eroded. The election of Lech Walesa to the presidency may, in part, be attributed to popular fears of enterprise closures and further unemployment.

Hungary, too, has been undergoing a macro-stabilization effort accompanied by structural reforms. The stabilization has been aimed at reducing inflation, running at about 27 percent annually, and to correcting an external imbalance, essentially to avoid a rescheduling of Hungary's large external debt. On the latter count, the program has clearly been successful, as a balanced current account is expected this year. Output is expected to fall by about 6 percent in 1990, in good measure because of the supply shock engendered by reduced trade with the Soviet Union. The level of unemployment has increased to about 80,000 in November, about 1.5 percent of the labor force; it is expected to increase to almost 200,000 persons by the end of 1991, as industrial restructuring is accelerated. The fast expanding private sector is, however, rapidly absorbing labor.

The stubbornness of inflation in Hungary remains a puzzle. It appears less a result of loose monetary policy than of enterprises, hit by multiple shocks during the year (devaluation, reduction in subsidies, declines in ruble trade, administered price increases), responding by raising prices, and not reducing them in the face of slack demand. Lowering inflation appears to require measures to increase competition in the economy and to hasten the exit of large, chronically insol-

vent enterprises that act as a source of substantial demand pressure. Although a number of small bankruptcies have been seen, there have been no bankruptcies of large enterprises.

Price and trade liberalization have also continued apace. In 1988, the share of consumer goods whose prices were freely set was slightly over 50 percent; it is expected to exceed 90 percent in 1991. Similar progress is evidenced in the liberalization of producer goods prices where, again, about 90 percent of prices will be freely set in 1991. On the trade front, less than 10 percent of imports are expected to be subject to licensing by the end of 1991. The average tariff in Hungary is about 16–18 percent, and there is discussion of reducing this to half its current level.

In reviewing the stabilization, price, and trade liberalization approaches of Hungary and Poland, it seems clear that Hungary has fended off precipitous declines in output, employment, and wages more successfully than Poland. This would appear to have less to do with the approach Hungary has adopted, or the specific measures undertaken, as to the vastly differing initial conditions. Poland has been tackling a near hyperinflation in which the credibility of the old bureaucracy to manage a gradual transition was minimal, and where there were strong political demands to institute irreversible changes; Hungary has not had to deal with these conditions. The experience, therefore, does not appear to be conclusive to either side of the gradualism vs. shock therapy debates.

II. Privatization

The sequencing of privatization in the reform efforts in East and Central Europe has aroused considerable controversy. It has been argued that, without private owners interested in the returns to capital, there will be little incentive for the dominant state enterprise sectors to vigorously pursue profit maximization, cut costs, and otherwise restructure their overmanned and inefficient enterprises. In view of the reluctance of politicians to close down insolvent enter-

prises, continued subsidies and ultimately recourse to credit creation will be necessary, both undermining the stabilization efforts and putting the overall reform programs in jeopardy. Full scale privatization should logically, therefore, come early in the reform effort, and preferably precede other measures.

Whatever the merits of this view, it is clear that, both in Hungary and in Poland, privatization is proceeding slowly. Both countries had initially to contend with worker beliefs that they owned the enterprises they worked in, a belief fostered by the establishment of enterprise councils dominated by workers in the 1980's. In both countries, the state has had to reestablish its ownership claims.

Before the major political changes this year, both Hungary and Poland witnessed a spate of "spontaneous" privatizations, where, typically, managers would imaginatively exploit loopholes in legislation designed to transform enterprises into joint-stock companies, appropriate for themselves majority shareholdings in enterprises, or else lease enterprise assets to themselves for minuscule rents. The practice was quickly ended by the new Polish government. In Hungary, there remains considerably greater tolerance for the practice, although early "scandals" led to a strengthening of the supervisory powers of the State Privatization Agency.

Both countries are advancing in their plans to privatize enterprises. A number of sales of enterprises to foreigners has already taken place in Hungary; a further 20 enterprises were brought to the market in September, and the government intends to sell about 10 percent of state-owned assets annually over the next 3 years. In Poland, political debate in the Sejm over the Privatization Law took about 6 months to complete. Frustration over the slowness of the process surfaced when Walesa made this a major campaign issue. It appears that a new privatization modality will be introduced in which some fraction of enterprise assets, perhaps 30 percent, will be given free through a voucher scheme to the population, about 20 percent will be offered to

employees at a considerable discount, and the remaining proportion retained or sold by the state. Proposals have also surfaced for developing holding companies that will have supervisory managerial powers over enterprises in which state holdings are large. Whether this will lead to a substantial acceleration in the pace of privatization and, as importantly, to improvements in enterprise performance, remains to be seen.

III. Enterprise Restructuring

Socialist enterprises are traditionally highly intensive in the use of materials and energy, are considerably overmanned, and provide a number of social benefits to employees that are generally reserved for state provision in market economies. This has resulted in low levels of efficiency and competitiveness in settings where most enterprises enjoy monopolistic or near-dominant market positions.

In opening economies to market forces and in enforcing "hard budgets," it has generally been expected that many enterprises would fail, and the majority of enterprises would have to undergo considerable financial, technological, and manpower restructuring before they could survive in the new market environment. Different views are heard as to the urgency of this requirement, its position in the sequencing of policy actions, and especially as to who should undertake it. In Czechoslovakia, for instance, the Finance Minister has emphatically declared that the state bureaucracy has no comparative advantage in restructuring enterprises; this activity should be left to the new private owners.

Both Poland and Hungary have, however, allowed a role for the state in restructuring. The Hungarian experience is much longer, dating back to 1986, when the process of restructuring a number of enterprises engaged in foreign trade was initiated. Although progress since has not been rapid, an acceleration is likely to be seen now as the number of liquidation proceedings brought by creditors against insolvent enterprises has increased substantially; bankruptcy will now afford greater prospects

for restructuring. In addition, the government has announced plans to independently initiate restructuring in certain sectors.

In Poland, the pace has been slower. An Enterprise Restructuring Fund has been established, based on a modest tax on enterprises. A Development Bank has been created, that will take equity positions in enterprises and provide technical and financial assistance in restructuring to its clients. By and large, however, restructuring in the first year of the Big Bang has been left to enterprises themselves, and as noted earlier, it is not clear how much has been made of the opportunity.

Enhancing competition in both economies has generally been left to occur through trade liberalization. However, both countries now have Competition Laws on their books and have targeted specific sectors for the initial attempts at demonopolization. Action may be expected in 1991, and may afford considerable opportunities for simultaneously speeding the privatization effort.

Social Safety Nets. The building of social safety nets (unemployment compensation, job training and vacancy referral systems, social security and pensions) has long been considered an essential component of reform programs, not simply from humanitarian concerns, but also to ensure political support for the program, and to facilitate labor mobility. Poland has not yet instituted a comprehensive system of social support, although some social benefits were introduced in the first year of the program. Legislation is now being prepared to provide adequate income support for the unemployed, while providing incentives to return to work, combined with a program to enhance the employability of those unemployed. A draft law on other social benefits is also now being prepared.

While the Hungarian unemployment provisions have been somewhat more generous, the expected large increase in unemployment in the coming year will require a forceful effort to develop nonbudgetary mechanisms for financing safety net programs. A draft bill has been submitted to Parliament, embodying proposals for compulsory contributions to an unemployment

insurance fund from both employers and workers, and discussions are taking place about revamping the social security systems of pensions, disability benefits, family allowances, and health care contributions.

Other Reforms. Although a number of other reforms are under implementation or being initiated, two deserve special mention. First, in both countries, financial sectors are being reformed through the establishment of two-tier banking systems, with the central bank hiving off its commercial activities to commercial banks proper. In both instances, major challenges exist in capitalizing the banks, and writing off non-performing loans, as well as strengthening institutional development through improved regulatory and supervisory capacities, and upgrading skills and developing services.

Second, on the fiscal front, Hungary has already instituted a VAT as well as a corporation and personal income tax. Poland continues to use a turnover tax system, but has plans to institute a VAT. The preparatory work for this does, of course take a long time and the tax is unlikely to be introduced before 1993.

IV. Conclusions

A thumbnail sketch of the content of reform programs in Poland and Hungary, and the issues of sequencing that have emerged, can hardly do justice to the complexity of the reform effort or to the multifaceted dimensions of the issues involved. A brief evaluation of some of the emerging lessons might nonetheless be attempted.

First, it has been noted that reforms are a "seamless web" in which each element is intimately related to every other, sometimes as a necessary precondition, sometimes as a facilitating requirement, and sometimes as a fortifying circumstance. In both Poland and Hungary, reforms in dismantling the pervasive reach of the command system in price and trade liberalization, and in the movement to exchange rate convertibility, have proceeded rapidly. Privatization, enterprise restructuring, demonopolization, building social safety nets, and institutional strengthening have, for understandable reasons,

lagged behind. These reforms do, however, remain essential components of the strategy to elicit a strong and positive supply response, realign production structures, increase economic efficiency, and foster the reallocation of resources. Failure to move rapidly ahead in these areas will not only delay the hoped for production response, but also put great pressures on governments to relax financial discipline that, if indulged, can only result in undermining the reform efforts.

Second, as a corollary because reforms are all of a piece, countries do not enjoy the luxury of doing one thing at a time. In this sense, because some reforms by their very nature will take longer than others to implement, it is important to act on as many fronts at once, and sustain a critical mass of reforms in order to ensure success. Issues of sequencing may, perhaps, derive considerable theoretical appeal from assumptions of instantaneous application and effect, while ignoring the practical constraints of politics, administrative capacity, and the time taken to design programs and implement them. When these considerations are entered into the debate, most sequencing issues dissolve, and one is left with the more prosaic judgment that reform efforts require multiple simultaneous actions on a variety of fronts.

Third, despite initial appearances, Poland and Hungary in 1990 do not present a good study in contrasts. Their previous experience with reform efforts does, however, appear to demonstrate that political commitment to a vision of the market economy is necessary for reforms to advance, and that because of the strong interrelationships between elements of reform programs, it is preferable to advance rapidly rather than gradually. The lessons from both countries are less important to each other than to other countries that are beginning their reform efforts, especially perhaps, the Soviet Union.

Fourth, the high hopes for quick reforms and quick turnarounds in economic performance do not appear to be realistic. The experience of both countries suggests that reform is going to take a very long time, and reform efforts will need to be sustained over

many years. Moreover, the Polish experience suggests that the social and economic costs of reform now appear to be much greater than originally anticipated.

Finally, a point only briefly touched upon, political support for reform programs by the populations of reforming countries are an indispensable requirement for sustainability and eventual success. This obviously raises great challenges for the newly elected politicians in the emerging democratic settings, both to educate populations about the magnitude of the difficulties and the reasons for policies, while avoiding the temptations of populism. No plausible alternative to the agenda of reform actions outlined above has indeed emerged.

Foreign Economic Liberalization in Hungary and Poland

By PAUL MARER*

Economic liberalization broadly defined means reducing the role of the authorities in microeconomic decisions, increasing reliance on the price mechanism rather than controls, establishing or strengthening market institutions, and integrating the country into the world economy. This paper deals with the last issue.

There is a close interconnectedness between liberalizing a country's foreign economic relations and changes in its domestic economy. Foreign economic relations that must be liberalized during the systemic transformation encompass relations among the countries of the Council for Mutual Economic Assistance (CMEA),¹ imports from convertible-currency areas, the convertibility of the currency, and foreign direct investment. I will focus on the first three issues.

I. Revamping the CMEA

The institutional mechanism of the CMEA that was in effect from 1950 until the end of 1990 was not compatible with the decentralized, market-driven economy toward which Hungary and Poland wish to progress.

Most trade decisions with CMEA partners were made by governments, bilaterally. Because domestic costs and prices were not market determined, and because the prices and the quantities of individual exports and imports were linked, it was not possible routinely to determine whether a transaction was in accordance with comparative advantage, especially for manufactures. Therefore, even in reformed economies such

as Hungary's, the state had to insure through taxes and subsidies that each transaction was profitable, up to a point, to each firm producing exports or using imports. There was no rationale to reward firms for improving the composition, quality, modernity, or after-sales service of exports, since it was very difficult to obtain from the trade partner's government a correspondingly better price or some other quid pro quo. This ossified the structure of intra-CMEA trade and weakened the abilities of firms to compete on the world stage.

Trade was conducted and settled in transferable rubles, a unit of account that was neither convertible nor transferable. Trade had to be bilaterally balanced. There was no point in generating a surplus whose value was uncertain, since it could be settled only by future shipments by the debtor. If the debtor country had goods it was willing to ship and the creditor wanted to buy, there would have been no surplus in the first place.

Yet, the Central and East European countries did benefit by being large net exporters of overpriced manufactures, and large net importers of underpriced energy and (some) raw materials in their trade with the Soviets. But these easy gains helped to preserve East Europe's excessively energy- and material-intensive structure of production and dependence on the Soviet Union as a supplier and as a market. The USSR was willing to incur some opportunity costs to trade with Eastern Europe in order to tie its trade partners into the Soviet-led Warsaw Pact political-military alliance.

Two aspects of intra-CMEA arrangements are separable. One is the system of pricing and settlement, that can be moved to current world market prices and settled in dollars without having to transform either partner's economic mechanism. The other is the system of foreign trade decision making. This is much more difficult to change be-

*Professor, International Business, Indiana University, Bloomington, IN 47405.

¹The CMEA was founded in 1949 by the USSR, Bulgaria, Czechoslovakia, Hungary, Poland, and Romania. East Germany joined in 1950; Mongolia, Cuba, and Vietnam later.

cause who makes foreign trade decisions and on what basis depends in large part on a country's domestic economic system. As long as, say, the USSR remains centrally planned, can Hungary or Poland set free their own enterprises to swim or sink in trading with the Soviets?

In the late 1980's, these issues were debated. It was clear that rapid transition to a new pricing, settlement, and trading system would create major shocks in Hungary, Poland, and the other economies of Central and Eastern Europe. At the same time, the changes would also help teach their firms how to swim, that is, to compete on the world market. Different CMEA countries, and experts in those countries, had different views on the tradeoff between the short-term costs and long-term gains of transition to alternative types of new arrangements (as detailed in Andras Kovcs, 1991).

In 1989, Hungary became the first country that, after arduous internal debates, officially recommended such a change, to be applied first in trade with the Soviets. But before Hungary could negotiate the full details of a new arrangement, in June 1990, Gorbachev announced that, beginning in 1991, Soviet trade with the CMEA countries will be valued at current world prices and settled in dollars. As the political rationale of keeping the Central and East European countries tied to the USSR has greatly diminished, and as the Soviet economy came to face immense difficulties, the main aim of the Soviet Union became to improve its terms of trade and earn more convertible currency.

A system of world market pricing and dollar settlement is equally compatible with profit-driven trade, with deals decided by firms alone, or with continued government involvement in enterprise decisions, without granting to firms the right to convert their earnings freely into commodities or hard currency. Soviet ideas seem to be closer to this second option. But as the Soviet Union is spiraling into ever-greater economic and political dislocations, individual republics, regions within the republics, and enterprises themselves are increasingly making their own barter foreign trade deals. These deals

are sometimes with counterpart agencies in the other countries, but are most often with individual exporters and traders.

During 1990, Poland's and Hungary's levels of intra-CMEA trade declined between 20 and 30 percent, not only with the Soviet Union but also with the other Central and East European countries. The largest decline was registered in trade with the former East Germany, where sales by West German firms supplanted much of what was formerly imported from CMEA partners. In Hungary and Poland, the authorities have imposed on firms restrictions on exporting to the CMEA, to prevent the accumulation of dubious credits.

The future of intra-CMEA trade is highly uncertain. Difficulties in the Soviet Union and in the other CMEA countries, together with the switch to dollar pricing and settlement, are sure to cause further large declines in trade volumes in 1991 and perhaps beyond. The system of trade is also uncertain; most likely, the arrangements will remain *ad hoc* and varied.

Apart from the decline in Hungary's and Poland's intra-CMEA terms of trade (with rough estimates of the loss running in the neighborhood of \$1 billion for each country), an even more serious adverse impact is the domestic multiplier effects of the declines in trade volumes. Although both countries will continue to reorient their trade to the West, the collapse of intra-CMEA trade and the change in the terms of trade will have large negative impacts on their economies in the short and medium run. But, if the new arrangements and pressures force enterprises to improve efficiency, change their production structure, and find new markets, then the collapse of the old CMEA can help set the stage for sustained economic recovery and integration into the world market.

II. Liberalizing Imports from the West

Until the late 1980's, Hungarian, Polish, and other Central and East European firms were almost totally protected from foreign competition. Protection was exercised not by quotas and tariffs, but through a complex and informal system of import rationing.

The logic of the system meant that all these economies pursued extreme versions of import-substitution industrialization. But, because building and operating the new capacities that were constructed to replace imports from the West required ever larger volumes of investment goods as well as basic and intermediate imports from the West, their foreign trade participation ratios and external dependence on the West increased, even though their policies intended to reduce dependence.

Owing to formal and informal domestic price controls, scarce imports from the West were not priced higher than domestic products or those imported from the CMEA countries. Thus, one cannot get a sense about the degree of protection in these countries by comparing prices on the domestic and foreign markets, as we do in market economies.

Another difference between Hungary and Poland on the one hand, and market economies on the other, is that in the former countries, a number of important "liberalization" steps have to be taken before import liberalization can begin in the sense that we use the term (i.e., allowing imports to compete with domestic production). One such step is ending the complete insulation of production from foreign trade. That is, importers should pay the actual costs and exporters receive the actual proceeds of their foreign transactions, and not the fixed domestic price, as is the practice under traditional central planning. In Hungary, this step was taken in 1968; in Poland, partly in 1972 and partly in 1982.

Another important "preliberalization" step is ending the monopoly of foreign trade, that is, the right of a single state-owned foreign trade company to conduct all export and import business in a given commodity, which is another feature of central planning. Such a system is usually dismantled gradually, first by giving foreign trading rights to a few, and then to a larger number of producing firms, and then by permitting first a few and then a larger number of foreign trade enterprises to compete against each other. In Hungary, the first halting steps were taken in 1968 when a handful of

industrial enterprises received exporting rights. In 1979, limited competition between foreign trading firms was introduced. The opportunity to engage in foreign trade as a right, not as a privilege, was granted to firms only recently. In Poland, this process began in the 1970's and proceeded slowly until December 1988, when a new law was passed, stating that every type of business is permitted that is not explicitly forbidden. In January 1990, virtually all remaining elements of the state monopoly of foreign trade were eliminated.

Import liberalization in a traditional sense began in Hungary in 1989. A 3-year program was adopted, at the end of which 80 percent of actual imports would be liberalized. To be sure, since a substantial segment of imports (in Hungary, Poland, and all the other Central and East European countries) are comprised of raw materials and parts that have no domestic substitutes, the share of domestic production that will be exposed to import competition will remain considerably less than 80 percent. Nevertheless, Hungary's move, taken at the time of severe balance-of-payments pressures, was pioneering.

Hungary's tariff levels and structures are close to the world average. The implicit quantitative restrictions (QRs) that characterized the old system were not converted into equivalent tariffs, even though an argument can be made that the authorities should have done so, temporarily, to ease the shock of long-protected enterprises suddenly being exposed to foreign competition. Nor were any extra tariffs or QRs introduced as instruments of industrial or trade policies, as they often are in the developing countries. Nevertheless, during 1989-90, imports did not surge because liberalization coincided with a soft domestic economy, a sharp decline in exports to the CMEA, and tight monetary policy.

In Poland, imports were liberalized in one fell swoop in January 1990. At the same time, a new import tariff was introduced, with an average *ad valorem* rate of 12 percent; on manufactures, 21 percent, with a wide dispersion of the rates. In addition to customs duties, imports also bear a hefty

turnover tax, replaced as of January 1, 1991, by a uniform value-added tax. Initially, some protection was also provided by the exchange rate.

The new customs law recognized that the impact of sudden competitive pressures may have to be mitigated in some sectors. Therefore, provisions were made for the easy temporary imposition of QRs, various surcharges, or simply higher tariffs. During 1990, such interventions did occur, for example, on imported cars and consumer electronics.

Fears that rapid import liberalization and the introduction of convertibility would lead to massive trade deficits did not materialize. On the contrary, Poland's convertible-currency trade moved from a small surplus of about \$100 million in 1989 to a whopping estimated surplus of \$3.5 billion in 1990. This was attributable to similar factors as those mentioned for Hungary, reinforced by extremely tight fiscal policies. During the first half of 1990, the accumulated budget surplus reached about 20 percent of total government expenditures, about 6 percent of the GDP. In turn, the surplus can be traced to 1) high profits of the enterprise sector, the result mainly of price liberalization under a highly monopolistic market structure; and 2) wage increases in the budget-funded sectors much below the rate of inflation.

III. Convertibility

Convertibility enhances efficiency because it helps to eliminate price distortions if domestic pricing and foreign trade policies are liberal enough to permit the importation of the international price structure. Under these conditions, most benefits of improved efficiency can be obtained if convertibility is assured for the domestic enterprise sector for current-account transactions.

With the substantial recent liberalization of imports (which means that enterprises that have the domestic-currency cover can purchase foreign currency freely to import liberalized goods), Hungary has taken a big step toward *de facto* convertibility of the kind mentioned. In addition, the National Bank of Hungary guarantees the convert-

ibility of profits that a foreign investor wants to repatriate, and also that of foreign capital invested, with certain restrictions. In 1988, generous foreign-currency travel allowances were provided to all residents. But, there was such a surge of travel (shopping tourism, mostly to neighboring Austria) that severe restrictions had to be reimposed to protect Hungary's precarious balance of payments. Thus, for the man on the street, the forint is not a convertible currency, even though it has many of the attributes of convertibility for resident enterprises and foreign investors.

The exchange rate of the forint is set by the National Bank of Hungary and is pegged to a currency basket. Concerned about inflation, that during the last several years has accelerated from single digit to about 40 percent in 1990, the Bank has maintained between 1987 and 1991 a real effective exchange rate (nominal effective exchange rate adjusted for relative movements in domestic prices and prices in the main trade-partner countries) that is considerably higher (fewer forints per dollar) than the marginal rate or the rate that the IMF would like Hungary to maintain. Export subsidies are thus still required.

In April 1989, Poland removed many restrictions on foreign-currency operations and introduced limited foreign exchange auctions. But the really important changes were introduced on January 1, 1990: a nearly 50 percent devaluation, from 6,500 zloty to the dollar to 9,500 to the dollar, pegging the zloty to the dollar, and making the currency internally fully convertible for all current-account transactions, without distinction between the enterprise and the household sectors. Western governments put together a \$1 billion stabilization fund (to which the United States contributed \$200 million) to support convertibility at the pegged exchange rate.

During January–May 1990, consumer prices rose 160 percent. This meant a substantial real revaluation of the zloty. But because 1), the initial devaluation allowed for *some* of the increase in prices; 2), highly restrictive monetary and fiscal policies, together with continued high inflation, caused large increased demand for zloty cash bal-

ances by enterprises as well as households; and 3), the large real depreciation of the dollar against other Western currencies meant that the zloty was de facto also depreciated, the exchange rate had remained stable throughout 1990, without the authorities having to impose foreign-exchange controls, and without a penny of the \$1 billion stabilization fund having to be touched.

To be sure, the fact that in 1990, Poland paid only about one-fifth of the interest due on its approximately \$44 billion foreign debt, and thereby "saved" having to buy foreign exchange equivalent of about 5 percent of GDP in foreign currency, had also contributed to the strength of the zloty.²

²Since 1981, Poland has not paid interest on debts owed to Western governments, which now stands at close to \$30 billion. Practically all of the \$15 billion increase in Poland's debt between 1981 and 1990 was due to this unpaid interest being capitalized. Early in 1990, the Polish government, assuming (incorrectly, as it turned out) that the country would run a trade deficit in 1990, made a unilateral decision to pay no principal or interest on its medium- and long-term commercial bank credits that were not rescheduled. However, it is servicing fully and promptly its rescheduled debts and trade credits. Poland's decision vis-à-vis the commercial banks has impaired its creditworthiness, discouraged Western banks from setting up branches in Poland, and slowed considerably the flow of Western direct investment.

The difference between Hungary, that serviced its large foreign debt fully, and Poland, that did not, is important to keep in mind in any economic comparison that one makes between the two countries.

IV. Conclusions

Poland's runaway inflation required a shock treatment to bring it under control, whereas Hungary's macroeconomic imbalance was not so great as to require such a treatment. Foreign economic liberalization was a key aspect of the package of stabilization measures Poland introduced in 1990; the very same measures are also important building blocks for the systemic transformation. In these areas, as well as on arrangements replacing the old CMEA mechanism, Poland and Hungary are moving on a rather similar path.

Derivation of "Rational" Economic Behavior from Hyperbolic Discount Curves

By GEORGE AINSLIE*

Recent research has discovered frequent anomalies in the utilitarian reasoning of the normal human adult (Amos Tversky and Daniel Kahneman, 1981; Richard Thaler 1987). One of these seems especially inimical to a rational market economy: the finding that peoples' preference for a smaller good vs. a greater but more delayed good often changes as a function of the time the choice is made, even though the difference in delay stays constant. For instance, a majority of adults report that they would rather have \$50 immediately than \$100 in 2 years, but almost no one prefers \$50 in 4 years over \$100 in 6 years, even though this is the same choice seen at 4 years' greater distance (see myself and V. Haendel, 1983, for a systematic study).

Such change of preference as a function only of elapsing time is not an isolated finding, but has been observed in undergraduates choosing between longer or shorter periods of access to a video game or relief from noxious noise; in women deciding whether or not to have anaesthesia for childbirth; in substance-abuse patients choosing between different amounts of real money; and even in animals choosing between two amounts of food at different delays (see my forthcoming study, ch. 3).

According to conventional utility theory, the value of delayed goods is discounted in an exponential curve; the curves from two alternative amounts of the same good available at different times should never cross in the absence of new information. How-

ever, when behavioral psychologists have conducted parametric studies of choice, they have found a radically different discount function that has become known as Herrnstein's matching law. Various experimental designs have given the curve a number of specific forms, but all are hyperbolic—more bowed than an exponential curve, so that preference for goods of different sizes at different delays will indeed change as a function of time. The best version of this discount curve for a single good is probably J. E. Mazur's (1987):

$$(1) \quad V = A / (\zeta + \Gamma(T - t))$$

where V is the good's value (its ability to compete with alternatives), A is its amount, T is the time at which each good is available, and t the time of the behavior that obtains it (so that $T - t$ is its delay from the moment of choice), ζ is an empirical constant that determines value at zero delay, and Γ is an empirical constant that modifies the steepness of the delay gradient. In the limited data available, neither constant seems to range far from 1.0.

If formula (1) is used to compare two goods separated by three units of time, the later good objectively twice as large as the earlier, the indifference point (where $V_{\text{later}} = V_{\text{earlier}}$) occurs when the earlier good is available two units of time from the moment of choice. At a delay of five units, the larger good is preferred by $2/(1+5+3) = 2/9$ to $1/(1+5) = 1/6$, while at one unit the larger good loses by $2/5$ to $1/2$. The smaller good is temporarily preferred to the larger when the delay is short.

Insofar as choice is governed by the matching law, a tendency to form temporary preferences will present a major obstacle to rational planning: Any plan requiring a pro-

*Veterans Administration Medical Center, Coatesville, PA 19320 and Jefferson Medical College. Suggestions by Elmer Schaefer, Margo Schaefer, George Loewenstein, and Drazen Prelec are gratefully acknowledged.

longed course of action will fail unless the person can arrange consistent motivation for or binding commitment to it. Looking at the long view, he may want to be generally thin, brave, and prudent, but to accomplish this, he will have to overcome strong desires for food, escape, and financial abandon in the immediate future. Ulysses and the Sirens will not be a remote fantasy but a central problem of life.

On the other hand, financial markets display a different pattern of human choice making. Participants behave as though they discount future goods at single digit, exponential rates, and they do so without having bound themselves to any obvious mast. But then, which is the "true" discount function—the matching law or the exponential rate available from the bank?

The evidence suggests some kind of mixture. Depending on the circumstances, ordinary people choose annual discount rates in the thousands (see my paper with Haendel) or hundreds (George Loewenstein and Thaler, 1989) of percent as well as the bank rate, and can be seen adopting committing devices that resemble the psychoanalysts' "defense" or "coping" mechanisms (my forthcoming study, ch. 5), as well as engaging in straightforward rational planning. Furthermore, a careful look at the implications of temporary preference formation suggests mechanisms by which a person who evaluates goods strictly according to the matching law can be expected to arrive at the banker's shallow exponential discount curves for at least some of his transactions, but imperfectly, as a result of varying skill and effort. These will be my topic.

I. Stability via Detection of Intertemporal Prisoner's Dilemmas

This mechanism is the personal rule, that can be derived from the matching law as follows: If an individual must make a series of choices between goods of amount A_i and later, larger goods of amount A'_i (i.e., all $A'_i > A_i$ and all $T'_i > T_i$), each choice will be described simply by the matching law evaluation of the two alternatives involved in that particular choice unless the choices are linked. If, however, the whole series of

FIGURE 1

choices must be made all at once in the same direction, then the choice will be governed by the summed values of the goods on each side. Looking at ratios of summed values, each derived from formula (1), the crucial time at which preference between the two whole series of goods changes will be represented by the t when the value V' of the series of larger goods equals the value V of the series of smaller ones, called t_{indif} :

$$\frac{V}{V'} = \frac{\sum A_i / (\zeta + \Gamma(T_i - t_{\text{indif}}))}{\sum A'_i / (\zeta + \Gamma(T'_i - t_{\text{indif}}))} = 1$$

If the choice is made before t_{indif} , it will favor the series of larger, later goods, and if it is made after t_{indif} it will favor the series of smaller, earlier ones.

This would be a trivial application of the matching law to the case of serial choices except for an important phenomenon: t_{indif} between the series of larger (primed) goods and the series of smaller (nonprimed) ones will move closer to the moment when the first smaller good is available as the series is made longer (see my 1975 article). The period of temporary preferences for the smaller good will be reduced or eliminated. Figure 1 shows this for the simplest case, two pairs of goods with both $A_i = A$ and both $A'_i = A' = 2A$. The curves show their

values at all times t before they are due. The period of temporary dominance by the smaller, earlier good is shorter when the curves from another pair are added (just before the left-hand pair) than when only one pair remains available (just before the right-hand pair). With appropriate mathematical transformations, this finding holds equally for streams of continuous reward as for discrete, momentary goods.

The practical effect of choosing a whole series of goods at once is thus to increase the individual's tendency to choose the larger goods. That is, a given small, early good can be available more imminently without his forming a temporary preference for it. This predicted phenomenon is obviously relevant to the problem of intertemporal consistency.

But how can a person arrange to choose whole series of goods at once? In fact, he does not have to physically commit himself. The values of the alternative series of goods cannot depend on whether he will actually get them, an event that has not yet occurred, but only on his expectation of getting them. Assuming he is familiar with the outcomes of his possible choices, the main element of uncertainty will be what he himself will actually choose. In situations where temporary preferences are likely, he is apt to be genuinely ignorant of what his own future choices will be. His best information is his knowledge of his past behavior under similar circumstances, with the most recent examples probably being the most informative. Furthermore, if he has chosen the smaller good often enough that he knows self-control will be an issue, but not so often as to give up hope that he may choose the larger goods, his current choice is likely to be what swings his expectation of future goods one way or the other. If he makes an impulsive choice, he will have little reason to believe he will not go on doing so, and if he controls his impulse, he has evidence that he may go on doing that. The same logic is the basis for what is called a "self-enforcing contract" between individuals (B. Klein and K. B. Leffler, 1981).

According to this logic, amplification of impulse control can be expected to occur to

some extent whenever a person perceives a series of confrontations with temptations as similar to each other. He will not necessarily notice the process itself, or develop any way of describing it. He may develop an extensive practical understanding of it by trial and error, but have only tangential theories about how it works. However, insofar as he has become aware of this phenomenon, he will be able to induce it where it has not occurred spontaneously, by arbitrarily defining a category of gratification-delaying behaviors that will thereafter prevail or not as a set (see my 1975 article).

Such personal rules can be seen as a solution to a bargaining problem. The temporary preference phenomenon creates a relationship among an individual's successive motivational states that can be described as limited warfare (T. C. Schelling, 1960): Successive motivational states have some interests in common, and others that are peculiar to them. The interests in common are identical with the person's long-range interest. The peculiar ones are short-range interests in whatever goods happen to be imminently available. At any given time, the alcoholic wants to drink less in the aggregate (he does not want to be an alcoholic), but he may want to drink a great deal currently. His long-range interest, common to all his successive motivational states, is to be generally sober; this interest is challenged, and often overwhelmed, by a succession of short-range interests in getting drunk just once.

To explore an everyday example: Say that a person at midnight faces the choice of staying up for two more hours and having fun before he finally gives in to fatigue, but feeling tired at work the next day, vs. giving up his present fun and expecting to feel rested at work. He values the imminent fun at 60 units per hour, and expects to lose 60 units per hour of comfort from when he gets up at 7 A.M. until he leaves work at 5 P.M. At midnight, the value of staying up will be

$$V_{up} = \sum_{i=0.5 \rightarrow 1.5} 60/(1+i) = 64$$

and the differential value of feeling rested at work will be

$$V_{\text{bed}} = \sum_{i=7.5 \rightarrow 16.5} 60/(1+i) = 49.$$

Given only this one choice, he will stay up and suffer the next day. However, if he faces this choice nightly, he may perceive his current choice as a precedent for future nights as well. Assuming he believes that he will go to bed on time on subsequent nights if he does tonight, and not otherwise, the values of his alternatives are

$$\begin{aligned} V_{\text{up}} = & \left(\sum_{i=0.5 \rightarrow 1.5} 60/(1+i) \right) \\ & + \left(\sum_{i=24.5 \rightarrow 25.5} 60/(1+i) \right) \\ & + \cdots \left(\sum_{i=216.5 \rightarrow 217.5} 60/(1+i) \right) = 78 \end{aligned}$$

for staying up on the next 10 nights, vs. (by similar calculation) 105 for going to bed early on the next 10 nights. He will go to bed, *if* he expects that he will thereby be motivated to follow suit on the subsequent nights.

Considering separately the present values of the alternatives in his first choice (64 vs. 49), and the present values of two subsequent series of 9 choices all in one direction (14 for always staying up vs. 56 for always going to bed), his incentives create a prisoner's dilemma between his own present and future motivational states (Table 1), one that he will face on a nightly basis. From his present point of view, going to bed on time both today and in the future is worth 105, and staying up both today and in the future is worth 78. However, if he can stay up today and still expect to go to bed on time in the future, that is worth 120. Conversely, if he goes to bed today but fails to also go to bed in the future, that is worth only 63. The latter two outcomes respectively represent his successfully finding a loophole that excepts the present case from the string of precedents, and falsely hoping

TABLE 1

Now	Future	
	Stay Up	To Bed
Stay up	64 + 14 = 78	64 + 56 = 120
To bed	49 + 14 = 63	49 + 56 = 105

that his current cooperation would give himself sufficient incentive to follow suit in subsequent choices.

The person's best move at present will thus depend on how he forecasts his future perceptions. Insofar as he sees his current choice as a precedent and not an isolated instance, he will face the incentives of a repeated prisoner's dilemma.

II. Factors Stabilizing a Person's Valuation of Money

The incentives to cooperate in an internal prisoner's dilemma will take us part of the way from the sharp fluctuations of matching law discounting to the prudence of rational investment. It is likely that valuations of financial transactions start out the same way as the valuations of the visceral goods like alcohol and sleep that have just been mentioned. Assume for instance that a person likes to skimobile in the winter and sail in the summer, that he is just willing to pay what each vehicle costs (\$1000 for a used model on which there is little annual depreciation) at the beginning of the season, and that he can sell each back to a store at the end of the season for 25 cents on the dollar. Then every 6 months, he will face the choice of getting \$250 immediately vs. saving \$1000 in 9 months, alternatives that formula (1) evaluates at \$250 and \$100, respectively, if $\zeta = 1$ month. If he actually sees this as an isolated instance, the matching law predicts that he will sell.

However, if he expects to face a similar choice twice a year for roughly the next 20 years, the incentives he faces are the sum of 40 \$250s, one immediate, the others discounted, vs. 40 \$1000s, each 9 months after the corresponding \$250. These contingencies, too, represent a prisoner's dilemma

TABLE 2

Now	Future	
	Sell	Hold
Sell	$250 + 167 = 417$	$250 + 489 = 739$
Hold	$100 + 167 = 267$	$100 + 489 = 589$

(Table 2). He will hold his equipment for next season, *if* he believes he must do so this time in order to continue doing so (i.e., if the upper right cell is not a credible outcome), *and* that he will continue to do so if he does so this time (i.e., if he does not see a great risk that the lower left outcome will occur).

Seeing a transaction as a member of a larger category somewhat dampens the fluctuations in spontaneous value predicted by the matching law. However, even the person who does this in the above example will be indifferent between selling and holding at a selling price of \$354, for a good that will be worth \$1000 to him in just 9 months. While people may sometimes buy and sell according to discount rates of such magnitude (the effective rates in Hausman's study of air conditioner purchases reached 89 percent; see Loewenstein and Thaler), it is still much higher than would be called either normal or prudent. We must appeal to three additional factors to produce the stability with which economists are familiar.

First, cash pricing makes a wide variety of transactions conspicuously comparable, and hence invites an encompassing personal rule about the value of money generally. Just as the person in the foregoing example achieved more constancy than he otherwise would by seeing his choices about the skimobiles as related to his choices about the sailboats, so he will become more constant still if he sees each of his financial transactions as a precedent for all others. That is, if he sees what he spends for food, clothes, movie tickets, toys, postage stamps, etc., as examples of wasting or not wasting money, he will add thousands of examples to his interdependent set of choices, each flattening his effective discount curve by a greater or lesser amount.

The ease of quantitatively evaluating and comparing all financial transactions lets the value of purchasable goods fluctuate much less over time than, say, the value of an angry outburst, or of a night's sleep. Accordingly, it is common to see someone swayed considerably more by today's emotional comfort than by next year's, but also common to see him behave as if today's wealth were worth only a tiny fraction more than next year's. However, an encompassing rule creates as a side effect the familiar sight of people pinching pennies lest they set a wasteful precedent. The stability that it brings about is apt to be insensitive to cost effectiveness.

Second, financial transactions tend to become rivalrous activities. This adds an additional stake to the intrinsic consumption value of the goods involved in these transactions. Unless the night owl robs his sleep so much that he snoozes at work, his discomfort is unlikely to become the basis for invidious distinctions between himself and his fellow citizens. However, in buying and selling, he is not choosing simply in parallel with his neighbors, but in competition with them. If some of them are prudent enough to buy his skimobile every spring for \$500 and sell it back to him every fall for \$1000, they will soon wind up richer than he, and rewards in power over him, not to mention the sweetness of victory, will be added to the goods that originally seemed to be at stake. Of course, rivalry may also make people rash; but if the relevant choices are perceived in series of precedents as above, they will further enlarge the motivation for deferral of gratification. It may be the need to defend at least rough comparability with one's peers that makes the credit card rate of 20 percent the indifference point for consumer interest, instead of 200. Conversely, it may be the relative invisibility of Japanese growth to American consumers that lets the latter continue to indulge in a 20 percent rate rather than setting a still lower one, despite the consequent transfer of wealth overseas.

Of course, a society often makes nonfinancial activities a basis of competition as well. Where people gain an advantage by

staying hungry to attain stylish slimness, or by cultivating sexual indifference to increase their bargaining power with partners who are more readily aroused, the personal rules governing these activities gain power from these additional stakes just as the rules governing the value of money do, and can sometimes motivate heroic acts of abstinence. However, just as cash pricing labels the largest number of a person's choices as comparable, so it engages the largest number of people in social competition.

Finally, a person can set up his personal rules so that investment decisions are not weighed against his strongest temptations. As H. M. Shefrin and Thaler (1988) have recently pointed out, people assign their wealth to different "mental accounts" such as current income, current assets, and future income. These accounts seem to represent personal rules for how readily the money they govern may be used to satisfy immediate wants (see my forthcoming study, ch. 7). Skillful designation of income as "investment" vs. "spending" money (or even less protected "pin" money) may permit a person to accept bank discount rates on some of his money, while still appeasing temptations that might overwhelm a monolithic rule. Thus an individual may evaluate goods in compartments, requiring investment rationality in one, abandoning himself to the matching law in another, and probably following intermediate rules in still others.

However, temptation can defeat this strategy not only by sheer intensity or immediacy (as some drugs notoriously do), but by motivating the search for loopholes in the rules that assign money to one account or another. In Shaw's *Pygmalion*, the ne'er-do-well Alfred P. Doolittle asks Professor Higgins for five pounds to spend on "one good spree for myself and the missus." The professor is charmed by Doolittle's hedonism and offers him ten, but Doolittle refuses. "Ten pounds is a lot of money: it makes a man feel prudent like; and then goodbye to happiness." Most rationalizations are less costly, but may still erode a person's will to maintain an account governed by conventional prudence, leading

perhaps to the compulsive spending syndromes that are so often observed.

Taken together, the mechanisms just discussed may account for why priceable goods are not usually evaluated simply according to the matching law, even though that law may underlie all valuations. I have argued that goods are assigned value according to their strategic importance in a repetitive, intertemporal prisoner's dilemma, cooperation in which may maximize objective income despite the vicissitudes of spontaneous preference. Such a process creates a special realm where discounting is shallow and exponential, a realm that exists as a special case of the matching law in much the same way that Newtonian physics forms a special case of relativistic physics. The consequence for utility theory is that most valuations are made not only or even mainly according to a present hunger, but according to the precedents they will set. If such a valuation process can sometimes make five pounds sterling worth more than ten, it may have the power to account for a number of other anomalies in utility theory as well; but that is another story.

Economic Analysis and the Psychology of Utility: Applications to Compensation Policy

By DANIEL KAHNEMAN AND RICHARD THALER*

Standard economic analyses often rely on the modern conception of the utility function that resembles a black box. People reveal their utility function through their choices. However, this modern view of utility is not the only possible conception. An earlier view, that associated utility with the pleasures of consumption, prevailed in economics from the days of Daniel Bernoulli and Jeremy Bentham and through the nineteenth century (George Loewenstein, 1991; George Stigler, 1950). We shall refer to this older notion as *experienced utility*, in contrast to the revealed preference notion we call *decision utility*. Since, experienced utility is presumably what people try to maximize and what welfare policies are about, the use of decision utility in economic analyses can only be justified if experienced and decision utility coincide. Recent psychological research, however, suggests several reasons why the concepts might in fact diverge (Kahneman and Carol Varey, 1991; Kahneman and Jackie Snell, 1990).

In this paper we try to illustrate the potential uses of an experienced utility concept by considering some aspects of compensation policy that would normally be ignored in a standard economic analysis. Such factors include the timing of payments over the course of the year, especially the use of lump sum bonuses, and the earnings profile over the worker's life. To a first approximation, the standard economic model assumes that the utility of a compensation package to a worker is invariant with respect to changes in details if the after-tax

present value of the payments is held constant. In this paper we argue for a richer and more psychologically realistic characterization of the quality of experiences that includes the following additional factors: adaptation, contrast, interpersonal comparisons, loss aversion, and fairness. If these factors are included, then it could be possible to create more worker satisfaction without increasing the cost of the pay packages—a free lunch.

I. Adaptation

What is the utility of an income stream? Does the temporal distribution of that stream affect the utility? Can workers be made happier simply by rearranging the timing of their paychecks? These questions are easily dismissed as trivial or meaningless. However, the convergence of evidence from survey data concerning income satisfaction and from psychological studies of adaptation suggests that the questions could be meaningful and the answers interesting. The central problem to be overcome is that of adaptation, the tendency to view that which is perceived as normal to be neutral, neither good nor bad. If people quickly adapt to whatever they are being paid, then no matter how high their salary rises, they never stay happier for long. We first review the evidence that this adaptation process is ubiquitous, and then consider what steps can be taken to mitigate its effects.

The essential results of many studies of income satisfaction and of the effect of income on self-reported happiness are summarized in three propositions (see Michael Argyle, 1987): 1) A cross-sectional study within any society at a particular time is likely to reveal a substantial correlation between income and satisfaction. 2) Societies that differ greatly in income nevertheless have very

*Professor of Psychology, University of California, Berkeley, CA 94720, and H. J. Louis Professor of Economics, Johnson School of Management, Cornell University, Ithaca, NY 14853, respectively. We thank George Loewenstein for helpful comments, and the Russell Sage Foundation for financial support.

similar mean levels of satisfaction. Furthermore, large changes of income level over time within any one society have no effect on income satisfaction. 3) Comparisons to others and especially to one's past determine the standard of satisfaction with income.

These results should probably not be dismissed as a mere artifact of verbal response, because they fit a broader class of observations—about adaptation and habituation to steady states (Harry Helson, 1964). Consider the familiar example of adaptation to temperature. As we all know, there is a substantial "comfort zone" within which we can adapt to temperature. The adaptation temperature is experienced as neutral, or hardly experienced at all. Temperatures that are higher or lower are experienced as hot or cold. To convince yourself of the power of the effect, prepare three pans of water: hot, cold, and tepid. Place one hand in the hot pan, one in the cold one. Wait a short while, then put both hands into the middle pan. One will feel hot, the other cold. This is an example of the phenomenon of adaptation. One of the functions of this mechanism is to maximize the throughput of information by treating a maintained state as a default or null state, and deviations of it as information to be signalled. In the context of hedonic experience (utility, happiness etc.), the phenomenon of adaptation has suggested to some that people are doomed to march forever on a hedonic treadmill (Philip Brickman and Donald Campbell, 1977). This pessimistic conclusion is in accord with the studies mentioned above, concerning the effects of income on welfare. It is also supported by Brickman et al.'s (1978) study of paraplegics and lottery winners. Surprisingly, once these two groups had become adapted to their new situations, they rated their own happiness quite similarly to other people.

It may be possible to defeat or at least retard adaptation, and in so doing, obtain more utils per unit of pay. To do so, however, we must exploit some relevant characteristics of the adaptation mechanisms (the plural is deliberate, because several distinct mechanisms serve the adaptation function).

Here we single out three of them.

1) To enhance the incidence or intensity of a particular sensation, it should be made intermittent over time (and scattered over space, if that dimension is relevant). Putting on red glasses is not a good strategy to obtain an intense experience of seeing red. Indeed, the most intense reds will be perceived in the spatial and temporal vicinity of contrasting greens. Contrast enhances experience. The implications of this point for various hedonic experiences should be obvious.

2) A single experience is less likely to alter the reference level if it is viewed as unusual or distinctive. This result is illustrated by a series of studies in which subjects judge the weight of each of a series of objects lifted, in sequence. In general, the geometric mean of the weights lifted becomes the adaptation level, and is perceived as neither heavy nor light. In some studies, subjects first lift (but do not assess the weight of) some "anchor stimulus" (such as a tray of objects) before every trial. A reliable finding is that the anchor affects the adaptation level, although not to the same extent as it would if it were made relevant to the judgment task. Thus, a heavy anchor will pull up the adaptation level. A more interesting finding is that the anchor has very little effect if it is qualitatively different from the stimuli judged in the series. If the anchor is made very distinctive and ostensibly irrelevant, it has no effect at all. These results suggest that a distinctive pleasurable event will not have a great impact on adaptation level. A bonus need not make the next paycheck appear painfully small.

3) Gradual changes and "spikes" have rather different effects on adaptation levels. Sudden changes are noticed and evaluated as a distinctive departure from adaptation, whereas a very slow gradual change will drag the adaptation level along with it, and may not even be detected.

The general conclusion is that it is certainly possible to use the same amount of money to produce different amounts of utility! The suggestion is that, for an income stream that is sufficient to prevent serious deprivation (compare comfort in the tem-

perature example), there exists a positively skewed distribution of the income over time that will yield greater utility than an even distribution. In particular, taking a portion of the compensation and paying it in a lump sum would appear to make things better.

To see whether this idea appeals to prospective employees, we conducted a small pilot study of attitudes about payment schedules. A group of Cornell University undergraduate students taking a class in psychology were asked whether they would prefer a salary of \$26,000 paid in weekly increments of \$500 or a salary of \$25,000 paid in equal weekly installments and a \$1000 bonus paid midyear. Nearly three-quarters of the subjects (73 percent) preferred the latter plan. (Larger bonuses were less popular.)

II. Side Effects of Bonuses: Saving and Splurging

Our discussion so far has treated the experienced utility of income as a criterion to be maximized. This is somewhat misleading, of course, because the utility of receiving a paycheck and the general sense of satisfaction with one's income are not what most people work for. The evaluation of a payment schedule implicitly invokes assumptions about the scheduling of consumption. Our argument therefore depends on the conjecture that people do not perfectly smooth their consumption when their compensation includes one or two fairly large increments to an otherwise even rate of pay. Instead, they tailor their routine expenses to their "normal" weekly or monthly income, with a different pattern of spending for the lump payments. Our second conjecture is that the altered pattern of expenditures is likely to be advantageous both to the workers and to the economy.

In 1976, Tibor Scitovsky used the principles of adaptation theory to develop an argument about the optimal use of income for consumption. He drew an interesting distinction between comforts, that become noticeable only when they are withdrawn, and pleasures—that are noticeable by definition. An essential condition for pleasure, in Scitovsky's analysis, is contrast with re-

spect to a norm. Feasts, vacations, and gifts are typical occasions for pleasure. Note that the occasion need not be unexpected—deviation from routine suffices. Scitovsky went on to present a rather jaundiced view of the American culture of consumption that appears to favor comforts over pleasures to a greater extent than many others. A significant aspect of the contrast between American and European patterns of consumption involves vacations, that are longer, more elaborate and relatively more costly in Europe. Scitovsky's argument (quite similar to ours above) is that there is a significant sense in which money expended on pleasures is better spent than money spent on comforts. We conjecture that substantial lump sum payments in December and in July would increase spending on pleasures.

Certain bonuses are also likely to increase saving. (There is no inconsistency here. Both pleasurable consumption and saving can increase if routine expenditures decrease. We are predicting that workers would save and splurge more at the expense of a slightly reduced normal standard of living.) A theoretical analysis based on the self-control aspects of saving is provided in Hersh Shefrin and Thaler (1988). They point out that individuals take actions to create their own lumpy payments. For example, a large majority of tax payers receive refunds, thereby giving the IRS an interest-free loan. Empirical support for the effect of bonuses on saving is presented in Tsuneo Ishikawa and Kazuo Ueda (1984). They estimated that in Japan, where most workers receive bonuses twice a year, the marginal propensity to consume bonus income is .437 compared to .685 for regular income. They also separated bonuses into anticipated and unanticipated components, and observed the same marginal propensity to consume from each.

III. Advantages to the Firm

We now turn to possible consequences of our sample proposal for the employing firm. We again concentrate our attention on arguments that would not generally receive much attention from the economics commu-

nity. The topics we consider are stimulating cooperation and increasing wage flexibility.

Stimulating Cooperation. The standard reaction by economists to the alleged incentive effects of profit-sharing schemes is to raise the so-called $1/N$ problem. In a large firm, a worker gets only a trivial portion of any increase in firm profits that he or she may produce, so the incentive to free ride will be strong. While it is possible to construct repeated play economic models in which cooperation is optimal, we agree with David Card's assessment: "I remain sceptical that simple economic models of individual self-interest can usually explain the effects of profit sharing" (1990, p. 141). Of course, the fact that economic theory predicts that profit sharing will have trivial incentive effects does not make it true. This prediction is much like other predictions of free riding. Yet we know that millions of people vote, clean up campgrounds, and donate to public television and other charities. Cooperation in public goods and prisoner's dilemma situations has also been extensively studied in the laboratory by social psychologists and experimental economists in recent years. Two main conclusions emerge from this research (summarized in Robyn Dawes and Thaler, 1988). First, cooperation is common even when the dominant strategy is to defect or free ride. Second, creating a group identity (such as by allowing the members of a group to talk to one another before making anonymous choices) fosters cooperation. It strikes us as plausible that profit-sharing plans can also contribute to the sense of solidarity that would improve worker performance. The empirical evidence gives some support to this view (see Edward Lawler, 1981, and the studies in Alan Blinder, 1990, and Ronald Ehrenberg, 1990).

Fairness and Wage Flexibility. One of the advantages of a Japanese-style bonus plan that Martin Weitzman (1984) has stressed is to create more flexibility in compensation policies and thereby reduce unemployment rates in recessions. Indeed, Richard Freeman and Weitzman (1987) do find that in Japan bonuses are more variable than base pay, and are also more highly

correlated with profits. From a theoretical perspective, it is hard to understand why this should be true. Put another way, why is it necessary to call some of the annual compensation a bonus to achieve greater flexibility? Why should this labeling matter?

Some of our research on perceptions of fairness, done in collaboration with Jack Knetsch (Kahneman et al., 1986), provides a possible answer. Respondents to a telephone survey were asked a series of questions about the perceived fairness of various pricing and wage-setting actions by firms. Three of our findings are germane to the issue of bonuses. 1) Pay cuts by profitable firms even in labor markets with high unemployment are judged to be very unfair. 2) Pay cuts that are occasioned by a deterioration in the competitive position of the employing firm are considered acceptable. 3) Cuts in remuneration are much more likely to be considered fair if they are described as the elimination of bonuses rather than as reductions in the regular wage rate.

The practical suggestion that emerges from this work is that the principle of wage flexibility will be most easily accepted by labor in a context of a gain- (and risk) sharing plan that uses periodic bonuses. If it became policy to encourage a move toward what Weitzman calls a share economy, this bit of psychological wisdom could become useful.

IV. Other Applications: Age Earnings Profiles

Many of the same psychological principles that we have used to argue for bonuses can also be used to explain the anomalous pattern of wages over the life cycle. Several authors have observed that while productivity typically peaks well before retirement, compensation often rises monotonically with age until retirement. Academic salaries are surely a case in point. Edward Lazear (1981) has argued that firms adopt this pattern to reduce shirking by older workers, but Robert Frank and Robert Hutchens (1990) find that the same pattern is observed for airline pilots, where agency problems would seem to be minimal. Frank-Hutchens and Loewenstein and Nachum Sicherman (1991)

both argue that the rising wage profile is better explained by worker preferences.

Adaptation, loss aversion, and self-control are important factors that help explain why workers prefer rising wage profiles. Because workers adapt to current levels of wages, and are particularly sensitive to reductions in their standard of living, a hump-shaped pattern mimicking productivity has obvious drawbacks. The modest positive slope actually observed in real terms, plus the nominal increases necessary to keep up with inflation, can also go a small way toward mitigating the hedonic treadmill. The costs of self-control must be invoked to explain why workers can't transform a hump-shaped wage profile into an increasing consumption profile.

V. Conclusions

Our discussion of the benefits of a bonus system to the workers has been deliberately provocative, raising points that are likely to appear bizarre to many economists, who are accustomed to think within the standard rational model. Our point, of course, is that this may not be the only way to think—and perhaps not even the best. We have made or implied the following assertions: (i) that spending habits will be affected by the temporal distribution of income flows, even when the timing and size of the variations in the flow are largely predictable; (ii) that people will have a preference for a moderate amount of lumpiness; (iii) that people may not be able to pick out the pattern of consumption that would maximize their "real" utility; they may both need and want help in this task.

A possible objection to the arguments we have raised is a familiar one: if a system of bonuses is so good, how come more firms do not use it? In Weitzman's book about the share economy, he responds to this question in part with a joke. How many economists does it take to screw in a light bulb? None. If it were a good idea to screw in the light bulb, someone would already have done it. While many other serious answers can be offered, including cultural and institutional factors, a deeper point may

have to do with the nature of maximizing. It is readily conceivable that a firm may have achieved a local maximum, such that any small adjustment that it makes will be detrimental. This does not imply, however, that there is no larger move that would get to a higher elevation. Consideration of the range of possible organizations of labor and pay suggests that the profit-maximizing firms of the standard model could well be trapped (even if completely successful at the game they are playing) at the peaks of rather lowly hills. This possibility is underscored by the fact that firms in other countries have successfully adopted the system under consideration.

Negative Time Preference

By GEORGE LOEWENSTEIN AND DRAZEN PRELEC*

The man who lives within his income is naturally contented with his situation, which, by continual, though small accumulations, is growing better and better every day. He is enabled gradually to relax, both in the rigour of his parsimony and in the severity of his application; and he feels with double satisfaction this gradual increase of ease and enjoyment, from having felt before the hardship which attended the want of them.

Adam Smith
The Theory of Moral Sentiments

Planning for the future invariably requires one to choose among alternative sequences of outcomes. Even simple short-term scheduling decisions about work, play, chores, vacations, etc., involve choosing between sequences, because events that take up time cannot be rescheduled without changing the timing of other activities.

Most economic analyses of preferences between temporally spaced sequences rely on the discounted utility model, along with the assumption of positive time preference and diminishing marginal utility.¹ Barring any preferential interactions across different time periods, the predictions of this model for determining the optimal sequencing of a given set of events are simple: Place the best event at the start, then proceed in descending order until the worst event is

reached at the end. Thus a declining series of consumption levels ought to be preferable to an increasing series, holding total consumption constant.

In this paper, we present a short selection of findings (reported more fully in our 1990 paper) that sharply contradict the normative sequencing rule just described. To most persons, a deteriorating series of utility levels is a rather close approximation to the *least* attractive of all possible patterns, regardless of the nature of events that are being ordered. As a secondary violation of the discounted utility model, the preferences of many people are not additive. Such additivity violations often reflect a concern for spreading utility levels evenly over time that is not attributable to diminishing marginal utility within periods.

I. Sequences vs. Simple Outcomes

Several recent studies have documented an apparently negative rate of time preference for choices among outcome sequences. Loewenstein and N. Sicherman (1991) found that a majority of museum visitors preferred increasing wage profiles over those that are flat or decline over time (holding total value constant). Pointing out that the flat and declining wage profile could produce a *dominating* consumption stream through a suitable savings program, did not have much impact on preference. C. Varey and D. Kahneman (1990) found that subjects strongly preferred brief sequences of decreasing discomfort, even at the cost of experiencing overall greater discomfort, while W. T. Ross and I. Simonson (1990) showed that people prefer sequences that end on a good note.

Preference for improvement is an overdetermined phenomenon, driven in part by anticipatory savoring and dread (Loewenstein, 1987), and in part by loss aver-

*Department of Social and Decision Sciences, Carnegie Mellon University, Pittsburgh, PA 15215, and Harvard Graduate School of Business Administration, Boston, MA 02136, respectively.

¹The applications of this model have been remarkably diverse, ranging from savings behavior, educational investment, labor supply, bargaining, to criminal behavior and addiction. In recent years, however, its descriptive validity has come under challenge (see our forthcoming article, and Loewenstein and Richard Thaler, 1990).

sion (A. Tversky and Kahneman, 1990) and habit forming changes in the adaptation level (J. Duesenberry, 1949). Savoring and dread contribute to the preference for improvement because, for gains, improving sequences allow decision makers to savor the best until the end of the sequence. With losses, getting the worst outcomes over with quickly eliminates dread. Adaptation and loss aversion induce preference for improvement because, over time, people tend to assimilate to ongoing stimuli and to evaluate new stimuli relative to their assimilation level. Thus, changes in, rather than levels of, consumption are the carriers of value. Improving sequences afford a continual series of positive departures (gains) from one's adaptation level; declining sequences provide a series of relative losses.

Savoring and dread apply to single outcomes as well as to sequences, but assimilation and loss aversion apply only to sequences. The fact that two motives operate for sequences but only one for simple outcomes suggests that the tendency to defer desirable outcomes will be stronger when those outcomes are embedded in sequences. Such a pattern is illustrated by a survey conducted with undergraduates at Harvard University, who were asked the following three questions:

1. Which would you prefer if both were free?
 - A. Dinner at a fancy French restaurant (86%)
 - B. Dinner at a local Greek restaurant (14%)

For those who prefer French:

2. Which would you prefer?
 - C. Dinner at the French restaurant on Friday in 1 month (80%)
 - D. Dinner at the French restaurant on Friday in 2 months (20%)
3. Which would you prefer?
 - E. Dinner at the French restaurant on Friday in 1 month and dinner at the Greek restaurant on Friday in 2 months (43%)
 - F. Dinner at the Greek restaurant on Friday in 1 month and dinner at the French restaurant on Friday in 2 months (57%)

We anticipated that more people would delay the fancy French dinner when it was combined in a sequence with the Greek dinner than when it was expressed as a single outcome prospect. This is indeed what happened. Of the 86 percent of subjects who preferred the fancy French dinner, 80 percent preferred a more immediate dinner (option C) over a more delayed dinner (option D). However, when the French dinner was composed into a sequence with the Greek dinner, a slight majority (57 percent) preferred to have the better dinner come later. Even with single-outcome events there is some motivation to defer the French dinner—witness the 20 percent of subjects who opted for the longer delay. However, this tendency is stronger for sequences than for individual items.

A similar pattern is observed when "Dinner at home" is substituted for the Greek dinner. Since most people eat dinner at home on most nights anyway, embedding the French dinner in an explicit binary sequence does not introduce any real modification of the problem, but the subject is reminded that the choice is "really" between complete sequences. Like other framing effects, such reminders cause preferences to shift, in this case in favor of the improving sequence.

II. What Is a Sequence?

If impatience and the desire for improvement are simultaneously present within a single individual, what determines the prepotent motive on a given occasion? A reasonable conjecture is that the desire for improvement depends on the "integrity" of the sequence—the extent to which the events that comprise it are of a similar type, are regularly spaced, and are not stretched too far apart.

The following example illustrates how the integrity of sequence can be reduced in a predictable way. Visitors to a science museum were asked to choose between alternative scheduling of two visits to a city where the respondent once lived, one to be spent with "an irritating, abrasive, aunt who is a horrendous cook," the other with "former

work associates whom you like a lot." Each subject made three choices, as described below. Response frequencies are reported in parentheses.

	This weekend	Next weekend	
A.	friends	aunt	(10%)
B.	aunt	friends	(90%)
	This weekend	26 weeks from now	
C.	friends	aunt	(48%)
D.	aunt	friends	(52%)
	26 weeks from now	27 weeks from now	
E.	friends	aunt	(17%)
F.	aunt	friends	(83%)

Observe that it is not possible to interpret the three modal choice patterns as the result of a *single* time preference function, denominated in absolute time. Responses to the first and third questions suggest a negative rate of time preference over a 1-week interval, irrespective of whether the week is close or far. By interpolation, one may conclude that the aunt would be scheduled in the earlier of *any* consecutive 2 weekends. Yet, for many subjects, the negative time preference over adjacent weekends does not compound into a negative time preference for the complete 6-month interval, as shown by responses to the second question.

Applied uniformly to all choices, negative time preference would require harsh reductions in present consumption in favor of the future. The fact that one does not observe such sacrifices, even given the additional inducements of a positive interest rate, is normally taken as evidence for positive time preference (M. Olson and M. J. Bailey, 1981).

We propose a different interpretation: Negative time preference is applied selectively, to those events that are seen as part of a meaningful sequence, having a well-defined starting and ending point. As the previous example shows, a pair of adjacent weekends defines a minimal but coherent

sequence, while a pair of weekends separated by 6 months does not.

The saliency of particular intervals is not an objective matter, but depends rather on perceptual framing. By deliberately manipulating the subjective frame, it is possible to induce normatively peculiar patterns of choices, as the following example shows. Subjects were asked to indicate their preferred times to eat two free dinners at the restaurant of their choice. One group was given no time constraint concerning when they could eat the dinners. A second, *constrained* group was told that the dinners must be consumed within the next 2 years. We anticipated that constrained subjects would prefer to delay the dinners more than unconstrained subjects, because the introduction of an explicit planning interval reminds the subjects that, by selecting a particular pair of dates, they are also choosing *not to consume* the meals on all of the other dates. As predicted, the mean preferred delay for the first dinner was 3.3 weeks for the unconstrained group and 7.7 for the constrained. Mean preferred delay times for the second dinner were 13.1 and 31.1 weeks.

These results are inconsistent with the axiom of revealed preference. The imposition of a time constraint on an initially unconstrained population should only affect the responses of that fraction of the population whose preferred delays are longer than permitted by the constraint. The population averages should, therefore, be longer in the unconstrained condition.

III. Nonadditive Preferences

Aside from a preference for improvement, choices between sequences also reveal a sensitivity to certain global or "gestalt" properties, having to do with how evenly the good and bad outcomes are arranged over the total time interval. Consider the following problem presented to 37 Yale University undergraduates (from Loewenstein, 1987). Subjects were first given a choice between A and B, then between C and D. Percentages choosing each of the options are presented in the right-hand column.

Alternative	Weekend 1	Weekend 2	Weekend 3	Choices
A	Fancy French	Eat at home	Eat at home	16
B	Eat at home	Fancy French	Eat at home	84
C	Fancy French	Eat at home	Fancy Lobster	54
D	Eat at home	Fancy French	Fancy Lobster	46

In the first problem, the majority of subjects preferred to postpone the fancy dinner to weekend 2, in keeping with the improvement principle. However, in the second problem, the insertion of the common lobster dinner in weekend 3 caused preference to shift slightly in favor of having the French dinner right away. This is a violation of additive separability, which implies that an individual preferring sequence A over B should continue to prefer A over B if any elements shared by the two sequences are altered in the same way.

Intertemporal additivity has never been viewed as normatively compelling, since there are many situations in which it is reasonable for consumption at one point in time to influence the marginal utility of consumption at another. Models of the "habit formation" type (Duesenberry; R. A. Pollack, 1970; G. M. Constantinides, 1990) assume that instantaneous utility depends negatively on past consumption. Other models incorporate the rate of consumption change into the utility function (R. Frank, 1989), or a preference/aversion for utility variation between adjacent periods, as in I. Gilboa's elegant formulation (1989).

Can the separability violation described above be reasonably attributed to some sort of loss aversion, following an adaptation to a reference point? An aversion to utility *reductions* from one period to the next would seem to work in favor of alternative D over C, while leaving preferences between A and B unchanged (to a first approximation). Hence it would predict the opposite violation pattern to the one actually observed.

Furthermore, we have observed the same preference pattern when common "Eat at home" weekends are inserted between the original weekends 1 and 2, and 2 and 3, in all four alternatives (thereby creating 5-weekend sequences). Because the neutral

filler weekends should reduce adaptation, and altogether eliminate differential interactions between adjacent periods, they should attenuate the separability violations. The results with the 5-weekend version of the problem were essentially equivalent, however: Only 11 percent of respondents opted for option A over B, while 49 percent preferred C over D.

The problem here is that habit formation/loss aversion models do not well capture the global properties that people find attractive in sequences. The relative advantage of sequences B and C is due to the fact that they both "cover" the 3-week interval better than their respective alternatives. In other words, they interleave the good and indifferent events in a more nearly uniform manner.

We have developed a theoretical model that measures both the degree of improvement and spreading of any sequence in terms of cumulative utility sequences (see our 1990 paper). The model defines improvement over time as the sum of deviations of the cumulative sequence that would be obtained by spreading total utility evenly over time from the cumulative utility stream of the sequence being evaluated. Evenness of spread is represented by the sum of the absolute value of these deviations.

The derivation of our notions of improvement and uniformity is depicted in Table 1, using the last illustrative example on the assumption that the "Eat at home" event has utility zero, and the "Fancy French" and "Fancy Lobster" events have utility one. Note that a simple preference for improvement would lead to a preference for B over A and D over C, while discounting alone would produce the opposite pattern. The desire for spreading outcomes over time, however, designated in the row marked Spread (lower numbers signify more even spreading of outcomes), can explain the preference for B over A and for C over D.

In several longer surveys (see our 1990 paper), we have systematically mapped out preferences over multiple period sequences. The judgments of the average person could be briefly described as follows: There is a strong liking for improving sequences, mod-

TABLE 1—DERIVATION OF IMPROVEMENT AND SPREAD MEASURES

	A	Alternative B	C	D
Sequence	1, 0, 0	0, 1, 0	1, 0, 1	0, 1, 1
Cumulative	1, 1, 1	0, 1, 1	1, 1, 2	0, 1, 2
Flat				
Seq.	.33, .33, .33	.33, .33, .33	.66, .66, .66	.66, .66, .66
Flat				
Cumul.	.33, .66, 1	.33, .66, 1	.66, 1.33, 2	.66, 1.33, 2
Difference	-.66, -.33, 0	.33, -.33, 0	-.33, .33, 0	.66, .33, 0
Improve- ment	-1	0	0	1
Spread	1	.66	.66	1

erated by a penalty for deviation from global uniformness, and a small premium for sequences that start well.

IV. Conclusion

Previous psychological work on time preference has focused almost entirely on the tradeoff that arises when two outcomes of different dates and different values are compared. The tacit premise was that such judgments will reveal an individual's "raw" time preference, from which one can then synthesize preferences over more complex objects—retirement plans, intertemporal income profiles, and such. This view we feel is fundamentally incorrect: As soon as an intertemporal tradeoff is embedded in the context of two alternative *sequences* of outcomes, the psychological perspective, or "frame" shifts, and individuals become more farsighted, usually wishing to postpone the better outcome to the end. The same person who prefers a good dinner sooner rather than later, if given a choice between two explicitly formulated sequences, one consisting of a good dinner *followed* by an indifferent one, the other of the indifferent dinner *followed* by the good one, may well prefer the latter alternative. Sequences of outcomes that decline in value are greatly disliked, indicating a negative rate of time preference.

A byproduct of the sequence frame is that subjects who are given a time interval, within which to schedule some enjoyable activity, may schedule it later on average

than people who are given no time frame at all. Apparently, as soon as the relevant interval is specified, a person becomes concerned with shifting the good events out to the end. This result has implications for life cycle choices; for example, it suggests the possibility that some individuals would choose an earlier retirement in the absence of a mandated retirement point.

The sensitivity of time preference to the sequence "frame" casts new light on the often-repeated charge that certain groups of people (consumers, managers, members of a particular nation or culture) have an excessively steep rate of time preference. Such a claim is a psychologically imprecise definition of the problem, at best. The differences that do prevail should instead perhaps be traced to different styles of mental book-keeping, which will alone produce different degrees of impatience even with a common underlying rate of time preference. Any operation, custom, or habit that causes the stream of purposeful activity to fragment into a series of isolated choices, each involving a simple intertemporal tradeoff, and each unrelated to a larger plan, encourages impatient choices. Whereas the integral sequence frame, by fusing events into a coherent sequence, promotes concern for the future, thereby creating an appearance of negative time preference.

Designing Economic Agents that Act Like Human Agents: A Behavioral Approach to Bounded Rationality

By W. BRIAN ARTHUR*

Most economists accept that there are limits to the reasoning abilities of human beings—that human rationality is bounded. The question is how to model economic choices made under these limits. Where, between perfect rationality and its complete absence, are we to set the “dial of rationality,” and how do we build this dial setting in to our theoretical models?

One approach to this problem is to lay down axioms or assumptions that suppose limits to economic agents’ computational ability or memory, and investigate their consequences. This is useful, but it begs the question of how humans actually behave. A different approach (the one I suggest here) is to develop theoretical economic agents that act and choose in the way *actual* humans do. We could do this by representing agents as using parametrized decision algorithms, and choose and calibrate these algorithms so that the agents’ behavior matches real human behavior observed in the same decision context. Theoretical models using these “calibrated agents” would then, we could claim, furnish predictions based on *actual* rather than idealized behavior.

It is unlikely there exists some yet-to-be-defined decision algorithm, some “model of man,” that would represent human behav-

ior in all economic problems—an algorithm whose parameters would constitute universal constants of human behavior. Different *contexts* of decision making in the economy call for different actions; and an algorithm calibrated to reproduce human learning in a search problem might differ from one that reproduces strategic-choice behavior. We would likely need a repertoire of calibrated algorithms to cover the various contexts that might arise.

Nevertheless, for a particular context of decision making, calibrating theoretical behavior to match human behavior would allow us to ask questions that are not answerable at present under the assumption of either perfect rationality or idealized learning. We might want to know whether a given neoclassical model with human agents represented by “calibrated agents” will result in some standard asymptotic pattern—a rational-expectations equilibrium, say. We might ask whether agents calibrated to learn as humans do converge to some form of optimality, or interactively to a Nash equilibrium.¹ And we might want to study the speed of adaptation in a particular economic model with human agents represented by calibrated agents.

What would it mean to calibrate an algorithm to “reproduce” human behavior? The object would be algorithmic behavior that reproduces statistically the characteristics of human choice, including the distinctive errors or departures from rationality that hu-

¹Drew Fudenberg and David Kreps (1988) and Paul Milgrom and John Roberts (1991) take a different, but parallel approach. They show that if human learning behavior fulfills certain axioms, asymptotic behavior will result in standard outcomes.

mans make, in the given context. Ideally, the algorithm could pass a Turing test of being indistinguishable from corresponding human behavior in the same context, to an observer who was not informed whether the behavior was algorithm generated or human generated (Alan Turing, 1956). This of course would be asking a lot.

This paper reports on and discusses my recent work (1990) that explores this idea of calibrating an algorithm to reproduce human behavior. It develops and calibrates a learning algorithm for a commonly encountered and simple decision context, that of agents choosing repeatedly among discrete actions with initially unknown, random consequences.

I. A Parametrized Learning Automaton

Consider the problem of iterated choice under uncertainty, in which a decision maker chooses one of N possible actions at each time that have random payoffs or profits drawn from a stationary distribution that is unknown in advance. This would be the case, for example, where a firm, government agency, or research department is faced each period with a choice among N alternative pricing schemes, or policy options, or research projects, each with consequences that are poorly understood at the outset and that vary from "trial" to "trial". The agent chooses one alternative at each time, observes its consequence or payoff, and over time updates his choice as a result. What makes this iterated choice problem interesting is the tension between *exploitation* of high-payoff actions that have been undertaken many times and are therefore well understood, and *exploration* of seldom-tried actions that potentially may have higher average payoff.

The classic multi-arm-bandit version of this problem is to design a learning algorithm or automaton that maximizes some criterion—such as expected average payoff. Our problem is different. It is to design a learning algorithm or learning automaton that can be tuned to choose actions in this iterated choice situation the way humans would.

Consider then a learning automaton that represents a single agent who can undertake one action of N possible actions at each time. We may think of "learning" in this iterated-choice context as updating the probabilities of taking each action on the basis of the payoffs or outcomes experienced. Action i brings reward $\Phi(i)$ that is unknown to the agent in advance, positive, and distributed randomly with a stationary distribution. The automaton (our artificial agent) "learns" via the following simple algorithm. It associates a vector of *strengths*, S_t , with the actions 1 through N , at each time t . The current sum of these strengths is C_t (the component sum of S_t), and the initial strength vector S_0 is strictly positive. The vector p_t represents the agent's probabilities of taking actions 1 through N at time t . At each time, t , the agent:

- 1) Calculates the probability vector as the relative strengths associated with each action. That is, it sets $p_t = S_t / C_t$.

- 2) Chooses one action from the set according to the probabilities p_t and triggers that action.

- 3) Observes the payoff received and updates strengths by adding the chosen action's j 's payoff to action j 's strength. That is, where action j is chosen, it sets the strengths to $S_t + \beta_t$, where $\beta_t = \Phi(j)e_j$; (e_j is the j th unit vector).

- 4) Renormalizes the strengths to sum to a value from a prechosen time sequence. In this case, it renormalizes strengths to sum to $C_t = Ct$.

This last step allows us to set the rate and deceleration of the learning via the parameters C and ν that are fixed in advance. The rate of learning, it turns out, is proportional to $1/(Ct)$. Parameters C and ν thus define a two-parameter family of algorithms that can be used to calibrate the automaton.

The algorithm has a simple behavioral interpretation (at least when $\nu = 0$). The strength vector summarizes the current confidence the agent or automaton has learned to associate with actions 1 through N . Confidence associated with an action increases according to the (random) payoff it brings in when taken. The automaton chooses its action with probabilities proportional to its

current confidence in the N actions, and learning takes place as these probabilities of actions are updated. The summed confidence in all actions is constrained to be constant. S_0 , the initial confidence in the actions, represents prior beliefs, possibly carried over from past experience.

It also has a machine-learning interpretation. A Holland-type *classifier* is a condition/action couple ("if object appears in left vision field/turn toward object"), where the action is allowed to be activated only if the condition is fulfilled (John Holland et al., 1987). If several classifiers have the same condition and that condition is fulfilled, they "compete" to be the one activated. Our algorithm can be viewed as a set of N classifiers each competing to be activated, where classifier j is the simple couple "if it is time to act/choose alternative j ." As is standard in classifier systems, strengths are associated with the classifiers; one classifier is triggered on the basis of current strengths; and the chosen classifier's strength is updated by the associated reward.

The algorithm is nonlinear in that actions that are frequently taken are further strengthened or reinforced, as in the classic Hebb's rule (Donald Hebb, 1949). And it is stochastic in that actions are triggered randomly on the basis of current probabilities, and rewards are drawn randomly from a distribution. Nonlinearity allows for the exploitation of "useful" actions—ones that pay well tend to be strengthened early on and therefore to be heavily emphasized. And the stochastic property (triggering actions randomly on the basis of their strength) allows for exploration: if a little used action brings in a "jackpot," it may be strengthened sufficiently to become a frequent action.

What can we say about the long-run properties of the learning implicit in this algorithm? Will it "discover" the maximal expected-payoff action, k say, and learn over time to activate it only in the limit? This is not obvious. There are two contradictory tendencies. On the one hand, if an inferior high-payoff action j is triggered early, it may gain in strength and be triggered ever more often until it dominates. Learning may

then fall into action j 's "gravitational orbit" without escaping. On the other hand, if exploration does not die away too fast, the algorithm will eventually uncover the fact that k is better and home in on it.

In my earlier paper (1990), I show that the algorithm has stochastic dynamics:

$$(1) \quad p_{t+1}(i) = p_t(i) + \alpha_t \left\{ p_t(i) \left[\phi(i) - \sum_j \phi(j) p_t(j) \right] + \xi_t \right\}.$$

The probability of choosing action i grows at a rate proportional to the difference between i 's expected payoff $\phi(i)$ and the average payoff at current probabilities, plus an unbiased perturbation term ξ . The step-size α_t is $1/(Ct^\nu)$. Further analysis settles optimality. If $\nu < 1$, the step-size remains large enough for inferior action j , emphasized early by chance, possibly to build up sufficient strength to shut k out. Optimality is in this case not guaranteed. If, on the other hand, $\nu = 1$, optimality is guaranteed. The step-size falls off at rate $1/t$; this delays movement to a nonoptimal action and retains exploration for a long enough time for k to be repeatedly activated and to dominate.

II. Calibration Against Human Subjects

We now want to calibrate the parameters C and ν against data on human learning. Here we are interested in three things: the degree to which the calibrated algorithm represents human behavior; whether the measured value of ν lies within the range that guarantees asymptotically optimal choices; and the general characteristics of learning (such as speed and ability to discriminate) that the calibrated values imply.

To calibrate the algorithm, I use the results of a series of two-choice bandit experiments conducted by Laval Robillard at Harvard in 1952–53 using students as subjects (reported in Robert Bush and Frederick Mosteller, 1955). I would prefer to calibrate on more recent experiments, but these have gone out of fashion among psycholo-

gists, and no recent, more definitive results appear to be available. I therefore use Robillard's data as an expedient, interpreting the resulting calibration as a good indication of human behavior in situations of choice rather than a definitive statement.

Robillard set up seven experiments, each with its own payoff structure, and allocated groups of ten subjects to each. Each subject could choose action *A* or *B* repeatedly in 100 trials; and the experiments differed in the probabilities with which unit payoffs occurred. For each experiment, Robillard reported the proportion of *A* choices in each sequential block of 10 trials, averaged over the group of ten subjects (for the data, see my 1990 paper).

I proceed by allowing "groups of artificial agents" (computer runs of the algorithm) to reproduce the equivalent of Robillard's data for fixed values of *C* and ν . The artificial agents produce *stochastic* sequences of choices or frequencies of choosing action *A*; hence goodness of fit to Robillard's data (under a suitable criterion) for fixed parameters is a random variable. I calibrate the parameters *C* and ν by minimizing the expected sum of errors squared between the automata-generated frequencies and the corresponding human frequencies for each particular experiment, totaled over the seven experiments. This results in $C = 31.1$ and $\nu = 0.00$. Note immediately that ν lies in a region where asymptotic optimality is far from guaranteed.

Figures 1 and 2 show the artificial agents' learning plotted against the human subjects' in four of the seven experiments, using these calibrated values. (The other experiments are similar in fit.) Judged by eye, the results are encouraging. The automata learn with roughly the same rate and variation as the humans in each of the experiments. Further statistical work (see my 1990 paper) shows that other data sets besides Robillard's produce similar fits, and that six of the seven Robillard learning trajectories could have been produced by the calibrated automata in the sense that each fits well within a distribution of 100 corresponding computed automata trajectories. (The outlier experiment, pictured second in Figure 2, has

FIGURE 1. CALIBRATED AGENTS' VS. HUMANS' CHOICE FREQUENCIES IN TWO EXPERIMENTS

Note: 50:0 denotes unit payoff with probabilities 50 and 0 percent.

FIGURE 2. CALIBRATED AGENTS VS. HUMANS IN TWO OTHER EXPERIMENTS

close-to-determinate payoffs, something humans notice faster than the algorithm.)

More convincing than statistical tests-of-fit are tests of whether the algorithm can replicate human behavior in quite different choice problems than those for which it was calibrated. A different problem is provided by recent experiments of Richard Herrnstein et al. (1990) where the distribution of payoffs to a choice is no longer fixed, but depends instead on the frequency of actions taken. These are of interest because in this frequency-dependent case, human subjects show a well-documented characteristic behavior called *melioration*; their choices converge not to optimal frequencies that maximize expected payoff, but to quite different frequencies that equalize expected payoffs of each action. In reproducing these experiments, I found that the calibrated agents perform similarly to the Herrnstein subjects; they also meliorate. That our algorithm picks up this characteristic of human behavior is not surprising. Both human and artificial agents carry out local search on the efficacy of choices at the current frequency of choice; thus in this frequency-dependent case both deviate from "rational" behavior in the same way. Findings like this give us confidence that we *can* indeed replicate human behavior for particular decision contexts with calibrated learning agents.

III. What About Optimality and Nash Equilibria?

Let us now put our calibrated agents to work. First, what they can tell us about the prospects for human choices converging to long-run optimality (in our standard, frequency-independent case)? Theoretically, we know from the zero-calibrated value for ν that optimality may not be reached on all occasions. But how often might this happen in practice?

To explore this, I set up a series of computer experiments (see my 1990 paper) designed around an iterated decision problem with six choices, each with uniformly distributed payoff from 0.5 to 1.5 times the choice's expected value. Expected payoffs fell off geometrically from action 1 to 6,

with action 1 the maximal choice. I found that as long as the best action was set to be more than 15 percent better than the next best, the algorithm locked in to it close to 100 percent of the time, in 100 repeated experiments. But when the best action's expected payoff was set at less than 10 percent or so more than the next best's, chance variations in received payoff caused choices to lock in to less-than-optimal outcomes in a significant percentage of experiments. Human choice, if captured by the calibration, appears to "discover" and exploit the optimal action with high probability, *as long as it is not difficult to discriminate*. But beyond a perceptual threshold, where differences in alternatives become less pronounced, nonoptimal outcomes become more likely.

It might be objected that this finding is merely an artifact of the algorithm I have chosen. I do not believe so. What is crucial to the emergence of the optimal action is a slowing down in speed of convergence, so that learning has time to "discover" the action with largest expected value. The data, not the algorithm, show this slowing down does not occur. I would thus expect the finding that long-run optimality depends on the difficulty of the problem to be validated under other well-fitting algorithm specifications. We could of course invoke an imagined discount rate to render lock-in to an inferior outcome "optimal over time." But this "discount rate" would then appear to be independent of the time between trials, and I find this argument unpersuasive.

A similar finding carries over to the question of whether human agents are likely to converge to a Nash equilibrium in an iterated game. Think now of our calibrated agents representing human agents learning within a normal-form, stage game (see my 1989 paper). The agents can observe their own actions and random payoffs, but are not particularly well informed of other players' actions and payoff functions. An example might be oligopolistic firms choosing among pricing policies in a decentralized market on the basis of observed end-of-quarter profit. Each agent then faces a multichoice bandit problem as before, and our

learning context carries over to this wider problem. Of course, in this case, each agent's payoff distribution changes slowly as other agents change their choice probabilities.

We can represent strategic learning here, for each agent separately, by the calibrated stochastic process in equation (1) and apply asymptotic probabilistic analysis to the resulting stochastic, dynamic model. Our results then represent human behavior in this context to the degree that the calibration captures actual human learning.

For some game-payoff structures, it turns out, strategies may not converge at all. The fact that each agent changes his choice probabilities (strategy profile) as other agents change *theirs* may cause strategy profiles to cycle. In games where learning *does* converge, the analysis shows a Nash outcome is likely but not assured. Nash requires that each agent converge to best reply; but with $\nu = 0$, there may not be sufficient exploration of strategies, and Nash is not guaranteed. In practice, as before, the likelihood of convergence to Nash depends on the difficulty of discrimination among the action payoffs.

How might we use calibrated agents to represent actual human adaptive behavior in other standard neoclassical models? My paper in progress with Holland, Palmer, and Tayler explores convergence to rational expectations equilibrium using calibrated agents in an adaptive version of the Lucas (1978) stock market. We find that the calibrated agents learn to buy and sell stock appropriately, and that the stock price indeed converges to small fluctuations around the rational expectations value. However, we also find that speculative bubbles and crashes occur—a hint that under realistic learning technical analysis may emerge.

IV. Conclusion

I conclude from this exploratory exercise that we can indeed design artificial learning agents and calibrate their "rationality" to replicate human behavior. Not only does the learning behavior of our calibrated agents vary in the way human behavior

varies as payoffs change from experiment to experiment in this repeated multichoice context, but it also reproduces two stylized facts of human learning well-known to psychologists: that with frequency-dependent payoffs, humans meliorate rather than optimize; and there is a threshold in discrimination among payoffs below which humans may lock in to suboptimal choices. Most usefully perhaps, the calibrated algorithm has a convenient dynamic representation that can be inserted into theoretical models.

To the degree that the algorithm replicates human behavior, it indicates that human learning most often adapts its way to an optimal steady state or, interactively, to a Nash outcome. But it also shows that humans systematically underexplore less-known alternatives, so that learning may sometimes lock in to an inferior choice when payoffs to choices are closely clustered, random, and difficult to discriminate among. Thus the question of whether human learning adapts its way to standard economic equilibria depends on the perceptual difficulty of the problem itself.

For choices among actions with initially unknown, random payoffs, it appears that behavior does not settle down much before 40 to 100 or more trials. This implies that there is a *characteristic learning time* for human decisions in the economy that depends both on the payoff structure of the problem and on the frequency of observed feedback on actions taken. There is also a time horizon over which the economic environment of a decision problem stays relatively constant. For some parts of the economy, the learning time may be shorter than the problem time horizon. These would be at equilibrium—albeit a slowly changing one. For other parts, learning may take

place more slowly than the rate at which the problem shifts. These parts would be always transient, always tracking changes in their decision environment, and never at equilibrium.

Experiments on Stable Suboptimality in Individual Behavior

By R. J. HERRNSTEIN*

In several recent experiments,¹ subjects made choices in a way that supports the idea that choice is governed, either sometimes or always, by a principle that does not necessarily maximize utility, as the subjects themselves would reckon their utility. In other words, they behaved irrationally, and their irrationalities seemed to be systematic and motivated, not just a matter of behaving carelessly or erroneously.

I. Representative Data

The subjects in the experiments worked for money by repeatedly choosing one of two alternatives in procedures in which the long-run pattern of choice interacted with the rate of payment for each alternative. The subjects earned less money than they could have, and they did so when there was no plausible compensating nonmonetary gain. Their suboptimality was often consistent with a principle of choice well established by hundreds of experiments mainly on animal behavior (Michael Davison and Diane McCarthy, 1988, Ben Williams, 1988; for related experiments on human subjects, see Christopher Bradshaw and Elemer Szabadi, 1988).

Subjects (mostly students) were recruited at the University of Chicago and Harvard University with posters announcing the possibility of earning a few dollars in a brief

session studying decision making. A subject sat in front of a computer monitor in a small, quiet chamber. The instructions explained that striking the left or right arrow on the keyboard would release a coin from one or the other of the two boxes portrayed on the screen. Each subject made about 300–400 choices of the left or right key for money, after about 100–200 practice choices under the same conditions. Striking the left or right arrow key always earned a coin worth one cent each with a probability of 1.0. The subject was told that payment would be equal to the total value of the coins earned, and also that it was a good idea to try to earn coins rapidly. From time to time, a message would appear on the monitor telling the subject how much time was left until the end of the session.

Figure 1 shows the contingencies of reward in experiment 1.² It shows the time taken for a coin to fall from the right and left boxes (R and L, respectively), as a function of preceding 40 choices that were of the right key. The dotted line is the average time weighted by the abscissa value. The open circles plot individual subjects and the right angle cross shows the average subject. On the vertical axis is the time (in seconds) for a coin to drop into reservoirs from either the left or right box. While one coin is dropping, no new coin could be earned. A session comprised $6\frac{2}{3}$ minutes of practice followed by 15 minutes earning money to keep.³ Coins fell at a speed that depended on the subject's recent choices.

The abscissa value is the proportion of right key choices in the subject's preceding 40 choices, hence updated after every choice. The time it took for a coin to fall depended on where along the x-axis the

*Department of Psychology, Harvard University, Cambridge, MA 02138. All of the experiments to be described grew out of an experimental design first used in the cited work, but much extended in discussions at the Russell Sage Foundation during 1988–89, with Ronald Heiner, George F. Loewenstein, Drazen Prelec, Howard Rachlin, and William Vaughan, Jr. The research was itself supported by the Russell Sage Foundation. The collaborators for particular procedures will be noted in turn.

¹See my paper with Drazen Prelec and William Vaughan (1986).

²This experiment was done by Vaughan, and myself.

³These times refer to elapsed times while coins were dropping, not continuous clock time.

FIGURE 1. EXPERIMENT 1

choice was made. Suppose the preceding 40 choices had been evenly divided between left and right keys and the subject chose the right key. It would take the coin almost 5 seconds to drop. A coin from the left box would have fallen in almost 3 seconds. Indeed, so long as the proportion of right choices in the preceding 40 trials is above .4, coins from the right box take 2 more seconds to fall than coins from the left. Below a proportion of .2, coins from the left box take 2 more seconds to fall than coins from the right. At a proportion of .3 choices of the right key, coins from either box take 4 seconds to fall.

The reward contingencies were chosen so that the weighted average time to drop, traced by the dotted line, was 4 seconds, no matter what the subject did. Consider the two extremes and the midpoint. At the midpoint, half the coins were taking about 5 seconds and half taking about 3 for an average of 4. At the extreme right, all the coins were falling from the right box and taking 4 seconds, and inversely at the left extreme, where all the coins were falling from the left box. For every point along the x -axis, the weighted average was 4 seconds. Given an averaging window of 40 trials, and an average of 4 seconds per trial, the subject could experience the entire reward functions in 160 seconds of coin-dropping time.

What is the rational strategy here? Indifference, which is to say, a 50–50 split, seems indicated, since all strategies earn equal amounts of money. Instead, of the 24 subjects in Experiment 1 and displayed in Figure 1, 22 came within a few percentage points of equalizing the falling speed of

right and left coins, which is at .3 on the x -axis.⁴ Each point shows the average allocation of a single subject during the latter half of the choices made by the subject during the one session he or she ran. The average of all subjects, shown by the crossed lines, was a 30.08 percent choice of the right.

Although the strategy is not rational in any obvious sense, it makes intuitive sense. Picture yourself in the situation and imagine that you find coins from the right box falling more rapidly than coins from the left. Consequently, you start choosing the right side more often. Gradually, coins from the right slow down and coins from the left speed up, and you find that those from the left are now falling more rapidly than those from the right. Your choices will now begin to swing back toward the left, since those coins are falling more rapidly. This strategy leads to an oscillation around 30 percent choice of the right key, and, judging from the data, it is the one adopted by virtually all our subjects. At 30 percent, the subject has equalized the average rate of returns from the two choices, namely a penny per 4 seconds. The equalizing of average rates of return from competing alternatives was first observed experimentally in 1961 in an experiment on pigeons earning bits of food (see my 1961 article). It has since been approximately confirmed in several hundred experiments on various species and is called the matching law because it calls for a match between the ratio of behavioral investments to the yield of those investments across all competing alternatives.

The process of comparing the rates of return and shifting toward the alternative that is currently yielding the better return is called melioration (my 1982 article; myself and Prelec, 1991; myself and Vaughan, 1980). Melioration has the inevitable effect of stabilizing in the vicinity of the matching law, and it also seems to be the process that

⁴Points deviate from the theoretical average line because, with the averaging procedure we used, the current ordinate value for a given proportion of right and left choices depends slightly on the precise sequence of choices within the previous 40 trials.

FIGURE 2. EXPERIMENT 2

most people spontaneously invoke when they are asked to describe their own choices.

Here is a second experiment.⁵ Again, volunteer subjects earn coins by striking left or right keys, the coins are worth one cent each, and the time to drop determines how much is earned in a 15-minute session. And again, the time to drop depends on the distribution of choices in the preceding 40 trials, as shown in Figure 2. The x-axis expresses the subject's previous 40 choices as a proportion of choices to the right key. The three lines of Figure 1 are perfectly superimposed in Figure 2. Whatever a subject has done in the preceding 40 choices, coins fall at the same speed from either box.

Suppose, for example, that a particular subject has divided his choices 50-50 and now makes a choice. Whether he chooses left or right, the coin will take about 3.6 seconds to fall. If he had been choosing only the left for the previous 40 trials, a coin from either the left or right would take 5 seconds to fall. The fastest possible speed is 3 seconds, which is what either the right or left coin would take if 30 percent of the preceding 40 choices had been of the right. Since the delays are always equal for right and left coins, the weighted average delay is also equal to them.

The most profitable strategy is at the lowest point on the line, where coins are all taking 3 seconds to fall. But instead of choosing right 30 percent, the 24 subjects are spread out broadly, approximating a 50-50 division between left and right. The

average choice, the crossed line, was 50.08 percent on the right. Many of the individual subjects are also near indifference, as well as their average. Indifference is what the process of melioration implies, for the average yield for left choices is always the same as that for right choices.

Melioration, rather than maximization, appears to have driven the subject's choices in these two experiments. In Experiment 1, melioration defined a particular allocation of choices, that subjects approximated, even though all allocations yielded equal overall earnings. In Experiment 2, maximization called for a particular allocation, but melioration did not; the subjects seemed to be indifferent to the effect of their allocations on earnings. The coin-dropping times involved in the two experiments were essentially the same. The sessions lasted equal times and the amounts of money were the same. In Experiment 1, a 2-second difference was enough to determine behavior; in Experiment 2, a 2-second difference was ignored. From these experiments, we could postulate that a 2-second difference controls behavior if, and only if, it is relevant to melioration.

But neither experiment pitted melioration against maximization in a way that would decisively affect earnings. In the first experiment, melioration caused the subject to obey the matching law when doing so had no effect on money. In the second, indifference to the two alternatives cost the subjects something like a half-second per choice, which may be considered negligible. Let us now consider a third experiment in which melioration implies the maximally *inefficient* allocation of choices.

The procedure is summarized in Figure 3.⁶ As before, the time taken for a coin to drop depends on the subject's choices. The abscissa here is the subject's allocation to the right key during the just-preceding ten choices. The entire reward functions could be experienced in a minute or less. Coins were again worth one cent. Coins from the

⁵Also by Vaughan and myself.

⁶Experiment by Loewenstein, Prelec, Vaughan, and myself.

FIGURE 3. EXPERIMENT 3

right box always took 2 seconds less to fall than coins from the left. However, the more choices there were of the right box in the preceding ten trials, the more slowly coins dropped from either box. The optimal strategy would have been to choose the left key on every trial (disregarding the negligible "end effect," which no subject exploited). Melioration dictates choosing right on every trial: it dictates maximal inefficiency. For the 56 subjects, the average chose the right on 82 percent of the trials. A large majority of subjects "learned" the least efficient strategy. At most, one subject discovered the maximizing strategy. Obeying the principle of melioration gets relatively expensive here.

II. Conclusions and Implications

In some of the procedures we have examined, the average performance is closer to maximizing earnings than here presented. For example, when the interaction between choice and consequence is more rapid (when the averaging window is, say, 3 or 6 preceding trials rather than 10 or 40), performance approximates maximization. This suggests an exceedingly limited capacity for taking account of the effect of one's own choices on marginal rates of return. In contrast, our subjects were quite sensitive to average rates of return, as shown by the close approximation to the matching point in Experiment 1.

Another factor appears to be the dimension of reward. Times rates of money, in the guise of a falling coin on a computer monitor, was the relevant dimension here. In other experiments, coin denomination has been the relevant dimension. When the pre-

ceding choices determined what the coins were worth, performances were closer to maximization. It takes a larger averaging window to produce a given degree of suboptimality with coin denomination as the reward dimension than coin rate.

Yet another class of factors affecting performance concerns the degree to which the alternatives are presented as discretely competing responses. The left and right arrow keys were perfectly correlated with coins dropping from left and right boxes, respectively. But when subjects were able to choose a certain proportion of coins from one box or the other, much like a subscription to left or right coins over some interval of time, performance shifted toward maximization. It seems that anything that makes it easier for a subject to redefine the response categories will make it easier to maximize.

For some experimental conditions, subjects span the range between maximization and matching. Individual differences have occasionally looked trimodal—with some subjects near the matching point, some near the maximizing point, and some near 50–50, perhaps indifferent or confused (or both). Intersubject variability seems to peak under conditions that are transitional between those producing maximization and those producing melioration. For example, as the averaging window is increased from, say, 6 to 40, the intersubject variability rises, then falls, as the average subject moves from maximizing earnings to obeying the matching law.

At the beginning of the paper, I suggested that the evidence points toward generically suboptimal human choice under at least some conditions, and possibly under all conditions. A word of explanation about the latter possibility seems in order, inasmuch as the evidence seems only to say that people are sometimes irrational in their choices, not that they are always irrational. But there is a difference between generic suboptimality and universal irrationality. It should be obvious that, for any situation for which a maximization strategy exists, there also exists a definition of response alternatives such that the process of melioration leads to maximization. Given this, it could

be argued that people are, in fact, always following the principle of melioration and that, when they are being rational, they are being rational only incidentally. This argument would be worth making only if there were also a well-developed theory of how a subject defines response alternatives, and we are not yet at that point.

Indeed, we do not know the learning algorithm that produces matching. Melioration implies a comparison of current average yields from competing alternatives, but beyond that vague characterization, the process remains to be explicated. At present, the prospects for doing so are unclear. We have examined the trial-by-trial choice patterns of our subjects and the only conclusion I can draw is that people appear to have many different ways to reach the matching point. Some subjects converge rapidly on an allocation, others scan the range of allocations more or less systematically, and still others do not behave in a way that allows simple characterization. For animal subjects as well, individual variation in the trial-by-trial choices is much greater than the variation around the matching point (see John Bailey and James Mazur, 1990). In the behavioral, as in the physical, sciences, the stable equilibria are often discovered before the dynamic processes that produce them.

Artificial Adaptive Agents in Economic Theory

By JOHN H. HOLLAND AND JOHN H. MILLER*

Economic analysis has largely avoided questions about the way in which economic agents make choices when confronted by a perpetually novel and evolving world. As a result, there are outstanding questions of great interest to economics in areas ranging from technological innovation to strategic learning in games. This is so, despite the importance of the questions, because standard tools and formal models are ill-tuned for answering such questions. However, recent advances in computer-based modeling techniques, and in the subdiscipline of artificial intelligence called machine learning, offer new possibilities. Artificial adaptive agents (AAA) can be defined and can be tested in a wide variety of artificial worlds that evolve over extended periods of time. The resulting *complex adaptive systems* can be examined both computationally and analytically, offering new ways of experimenting with and theorizing about adaptive economic agents.

Many economic systems can be classified as complex adaptive systems. Such a system is *complex* in a special sense: (i) It consists of a network of interacting agents (processes, elements); (ii) it exhibits a dynamic, aggregate behavior that emerges from the individual activities of the agents; and (iii) its aggregate behavior can be described without a detailed knowledge of the behavior of the individual agents. An agent in such a system is *adaptive* if it satisfies an additional pair of criteria: the actions of the agent in its environment can be assigned a value (performance, utility, payoff, fitness, or the like); and the agent behaves so as to increase this value over time. A complex adaptive system, then, is a complex system

containing adaptive agents, networked so that the environment of each adaptive agent includes other agents in the system.

Complex adaptive systems usually operate far from a global optimum or attractor. Such systems exhibit many levels of aggregation, organization, and interaction, each level having its own time scale and characteristic behavior. Any given level can usually be described in terms of local niches that can be exploited by particular adaptations. The niches are various, so it is rare that any given agent can exploit all of them, as rare as finding a universal competitor in a tropical forest. Moreover, niches are continually created by new adaptations. It is because of this ongoing evolution of the niches, and the perpetual novelty that results, that the system operates far from any global attractor. Improvements are always possible and, indeed, occur regularly. The everexpanding range of technologies and products in an economy, or the everimproving strategies in a game like chess, provide familiar examples. Adaptive systems may settle down temporarily at a local optimum, where performance is good in a comparative sense, but they are usually uninteresting if they remain at that optimum for an extended period.

A theory of complex adaptive systems based on AAA makes possible the development of well-defined, yet flexible, models that exhibit emergent behavior. Such models can capture a wide range of economic phenomena precisely, even though the development of a general mathematical theory of complex adaptive systems is still in its early stages.¹ The AAA models complement current theoretical directions; they are

*Professor of Psychology and Computer Science and Engineering, University of Michigan, Ann Arbor, MI 48109; and Assistant Professor of Economics and Decision Sciences, Carnegie Mellon University, Pittsburgh, PA 15213, respectively; both are External Professors, Santa Fe Institute, Santa Fe, NM 87501.

¹It is important in this research to determine just where the potential for general solutions exists. There are simple models of cellular automata, for example, wherein the solutions to particular questions are computationally irreducible—the shortest way to analyze the system is to run the complete computation.

not intended as a substitute. Many of the most interesting questions concern points of overlap between AAA models and classical theory. As a minimal requirement, wherever the new approach overlaps classical theory, it must include verified results of that theory in a way reminiscent of the way in which the formalism of general relativity includes the powerful results of classical physics.

I. Why Study Artificial Adaptive Agents?

The AAA models have several characteristics that are not available in traditional modeling techniques. Models based on pure linguistic descriptions, while infinitely flexible, often fail to be logically consistent. Mathematical models lose flexibility, but gain a consistent structure and general solution techniques. The AAA models, specified in a computer language, retain much of the flexibility of pure linguistic models, while having precision and consistency enforced by the language. The resulting models are dynamic and are "executable" in the sense that the unfolding behavior of the model can be observed step by step. This makes it possible to check the plausibility of the behavior implied by the assumptions of the model. The precision of the definitions also opens AAA models to mathematical analysis. The ability to explore a wide range of phenomena involving learning and adaptation, linked with the rigor imposed by a computer language, provides a powerful modeling technique.²

The AAA models offer a way of approaching one of the major questions of present theory. Current theoretical constructs, based on optimization principles, often require technically demanding derivations. It is an obvious criticism of these constructs that real agents lack the behavioral sophistication necessary to derive the proposed solutions. This dilemma is resolved if it is postulated that adaptive mechanisms, driven by market forces, lead the

agents to act as if they were optimizing (see, for example, Milton Friedman, 1953). AAA explicitly model this link between adaptation and market forces, and can thus be used to analyze the conditions under which optimization behavior will (not) occur.

Insofar as human behavior is driven by adaption, an understanding of AAA may prove to be a useful benchmark for, and provide insights into, existing human experiments (see, for example, J. A. Andreoni and Miller, 1990; Brian Arthur, 1990).³ An experiment consisting of artificial agents allows the utility, risk aversion, information, knowledge, expectations, and learning of each subject to be carefully controlled. Moreover, at any point in the experiment, the knowledge and learning of the artificial agents can be "reset" to any desired previous state, and subtle variations of the environment can be analyzed. The strategy (as well as the behavior) of the AAA can always be explicitly analyzed, something not usually possible with human subjects. Finally, the infinite patience and low motivational needs of AAA "subjects" implies that large-scale experiments can be conducted at a relatively low cost.

A major feature of AAA models is their ability to produce emergent behavior. A wide variety of behaviors can arise endogenously, even though these behaviors, as with any model, are constrained by the initial structure. The possibilities are so rich that it is often difficult to predict on a priori grounds what behaviors and structures will emerge. It thus becomes possible to explore realms that were unanticipated when the model was defined. Analysis of these emergent phenomena should offer both insights and suggestions for new theorems about the effects of adaptive agents in economic systems.

The AAA models may also prove useful in studying economic systems that have either an absence or a plethora of theoretical solutions. Many important economic prob-

²Programming even a simple market is instructive on the limitations of both the pure linguistic and mathematical approaches.

³Artificial agents could also be used as "subjects" in pilot studies to identify potentially interesting new human experiments.

lems, such as double-auction strategies, multisectoral general equilibrium models, and the like, have no easily derived analytic solutions. Several AAA techniques were originally designed as optimization methods for environments that are nonlinear, noisy, discontinuous, or involve enormous search spaces. As a result, they offer useful numerical techniques for such problems in economics. At the opposite extreme are systems with multiple solutions. For example, in repeated games, the Folk theorem often admits a vast number of potential solutions. In these cases, the interaction of the adaptive systems with the economic environment may narrow the set of potential solutions. Different equilibria may have different degrees of *adaptive complexity*.

Beyond complementing current theoretical and empirical work, AAA offer the potential for unique extensions of current theory. The mechanisms generating the global behavior of a complex adaptive system can be directly observed when the computer is an integral part of the theory. For such theories, the computer plays a role similar to the role the microscope plays for biology: It opens up new classes of questions and phenomena for investigation. Problems that prove difficult for traditional mathematical approaches are often easily implemented as an AAA system. In that form, they can be dissected and modified with ease, providing new opportunities for theory generation and testing. More generally, the potential for the development of a general calculus of "adaptive mechanics" exists. A calculus of these systems would combine the advantages of analytic perspicacity with computer-driven hypothesis testing.

II. Some Current Artificial Adaptive Agent Techniques

A wide range of computer-based adaptive algorithms exist for exploring AAA systems, including classifier systems, genetic algorithms, neural networks, and reinforcement learning mechanisms. The multiplicity of techniques presents a problem for analysis. How sensitive are the results to a particular incarnation of the adaptive agent? This

problem, of course, confronts any attempt to lessen the rationality postulates traditionally used in economic theory. Usually, there is only one way to be fully rational, but there are many ways to be less rational. It is important in building a theory based on AAA to construct agents that exhibit robust behavior across algorithmic choices. Current economic studies of adaptive agents rely on genetic algorithms (R. M. Axelrod, 1987; Miller, 1989; Andreoni-Miller) and classifier systems (R. Marimon et al., 1990; Arthur).

Genetic algorithms (GAs) were developed by Holland (1975) as a way of studying adaptation, optimization, and learning. They are modeled on the processes of evolutionary genetics. A basic GA manipulates a set of structures, called a *population*. Structures are usually coded as strings of characters drawn from some finite alphabet (often binary). For example, in a game context, a string might be interpreted either as a simple strategy (a rule table) or as a computer program for playing the game (a finite automaton). Depending upon the model, an agent may be represented by a single string, or it may consist of a set of strings corresponding to a range of potential behaviors. For example, a string that determines an oligopolist's production decision could either represent a single firm operating in a population of other firms, or it could represent one of many possible decision rules for a given firm. Whatever the interpretation, each string is assigned a measure of performance, called its *fitness*, based on the performance of the corresponding structure in its environment. The GA manipulates this population in order to produce a new population that is better adapted to the environment.

In execution, a GA first makes copies of strings in the population in proportion to their observed performance, fitter strings being more likely to produce copies. As a result, fitter strings are more likely to contribute to the new population. After the copies are produced, they are modified by the application of genetic operators. The genetic operators provide for the introduction of new strings (structures) that still

retain some of the characteristics of the fitter strings in the parent population.

The primary genetic operator for a GA is the *crossover* operator. The crossover operator is executed in three steps: 1) a pair of strings is chosen from the set of copies; 2) the strings are placed side by side and a point is randomly chosen somewhere along the length of the strings; 3) the segments to the left of the point are exchanged between the strings. For example, crossover of 111000 and 010101 after the second position produces the offspring strings 011000 and 110101. Crossover, working with reproduction according to performance, turns out to be a powerful way of biasing the system toward certain patterns, *building blocks*, that are consistently associated with above-average performance.

It can be proved (see Holland, 1975) that GAs are a powerful technique for locating improvements in complicated high-dimensional spaces. They exploit the mutual information inherent in the population, rather than simply trying to exploit the best individual in the population. We can liken each of the potential building blocks to one arm of an n -armed bandit. Under this interpretation, each successive generation samples the building blocks in a way that closely corresponds to the optimal solution of an n -armed bandit problem. The GA learns by biasing the search toward combinations of above-average building blocks. Reproduction and crossover are very simple operations that impose low-information and processing requirements on the agents employing them.

A *classifier system* (CS) (Holland et al., 1986) is an adaptive rule-based system that models its environment by activating appropriate clusters of rules. It uses a GA to revise its rules. Each rule is in condition/action form, and many rules can be active simultaneously. The action part of a rule specifies a message that is to be posted when the rule is activated. The condition part of a rule specifies messages that must be present for it to be activated. Thus, each rule is a simple message-processing device that emits a specific message when certain other messages are present. Overt actions affecting the environment are the result of

messages directed to the system's output devices (effectors), while information from the environment is received via messages generated by its input devices (detectors). The overall system is computationally complete in the sense that any program written in a programming language, such as FORTRAN, can also be implemented by a CS.

A CS-rule does not automatically post its message when its condition part is satisfied. Rather, it enters a competition with other rules having satisfied conditions. The outcome of this competition is based on a quantity, called *strength*, assigned to each rule. A rule's strength measures its past usefulness, and it is modified over time by one of the system's learning algorithms (see below). There may be more than one winner of the competition at any given time—hence a cluster of rules can react to external situations. A CS operates on large numbers of rules, with a small number of simple, domain-independent mechanisms. It provides emergent, learned capabilities for reacting to its environment.

A CS adapts or learns through the application of two well-defined machine-learning algorithms. The first algorithm, called a *bucket-brigade algorithm*, adjusts rule strengths. Each rule is treated as an intermediate producer in a complex economy, buying input messages and selling output messages. When a satisfied rule R succeeds in the competition to post its own message, it pays the rule(s) that supplied the messages satisfying its condition part. This amount is subtracted from R 's strength. On the next time-step, if other rules are satisfied by R 's message, and win the competition in turn, then R receives the rules' payment. R 's strength is increased accordingly. The net effect of the two transactions is R 's profit (loss). Some rules also act directly on the environment in a way that produces direct payoff from the environment to the system. Their strength is increased in proportion to that payoff. A rule's strength will increase over time only if it earns a profit, on average, in these transactions. Generally this happens only if the rule directly produces payoff, or else belongs to one or more causal chains leading to payoff. Under appropriate conditions, the

strengths assigned by the bucket-brigade algorithm do converge to a useful measure of the rule's contributions to system performance (Holland et al.).

In order to generate and test new approaches to the environment, the CS needs a second learning algorithm, a *rule discovery algorithm*. A GA can be used for this purpose, because the rules of a CS can be represented by strings in an appropriate alphabet, and a rule's strength amounts to a measure of its performance. The GA, by forming new rules in terms of tested, above-average building blocks, transfers experience from the past to new situations. Plausible new rules result—rules to be tested and retained or discarded on the basis of their ability to enhance the performance of the CS.

Under the combined effects of the bucket-brigade and genetic algorithms, rules become coupled in complex networks. Clusters and hierarchies of rules emerge. Over time, these substructures serve as building blocks for still more complex substructures. A CS agent can: 1) generate broad categories for describing its environment (so that experience can be brought to bear on novel situations); 2) progressively refine and elaborate the relation between categories (using experience to make distinctions and associations not previously possible); 3) use these categories to build internal models that supply the agent with expectations about the world; 4) treat all internal models as provisional (subject to confirmation or refutation as experience accumulates); and 5) generate new hypotheses that are plausible in terms of accumulated experience. Moreover, because of the bucket-brigade algorithm, these activities can proceed in an environment where payoff is intermittent or rare. Such capacities enable a CS agent that is not omniscient to act with increasing rationality.

III. Towards a Mathematics of Complex Adaptive Systems

A mathematical calculus appropriate to the study of complex adaptive systems must meet distinctive requirements. The usual mathematical tools, exploiting linearity,

fixed points, and convergence, provide only an entering wedge. In addition we need a mathematics that works in close conjunction with computer modeling techniques—one that puts more emphasis on combinatorics and algorithms. We require techniques that emphasize the emergence of structure, particularly internal models, through the generation, combination, and interaction of building blocks. The present situation seems quite similar to that of evolutionary theory prior to the development of a mathematical theory of genetic selection (R. A. Fisher, 1930).

Though there is nothing like an overall theory, there are some extant pieces of mathematics that are relevant. The schema theorems for genetic algorithms (Holland, 1975) offer some insight into processes that discover and recombine building blocks. It appears that schema theorems are special cases of a much more general formulation of the effects of recombination in evolution. This formulation should bring some of the more sophisticated tools of mathematical genetics to bear on adaptive agent models. Mathematical work aimed at understanding the evolution of CS may also be useful. The progressive development of hierarchical organization can be treated as the addition of levels to a quasi homomorphism (Holland et al.).

Perpetual novelty can be modeled by a regular Markov process in which each of the states has a recurrence time that is large with respect to any feasible observation time. Equivalence classes can be imposed and used as the states of a *derived* Markov process (Holland, 1986). Work by Miller and S. Forrest (1989), based on S. A. Kauffman's (1984) studies of random graphs, provides additional insights into the emergent structures of CSs.

IV. Conclusions

The AAA research complements ongoing theoretical and empirical work, allowing exploration and analysis of previously inaccessible phenomena. What are the future prospects for this line of inquiry? Early work with AAA in economics has shown that they can acquire sophisticated behavioral patterns. Observation of the course of learning

in these AAA has already increased our understanding of some economic issues. Even limited AAA open up new avenues for analyzing decentralized, adaptive, and emergent systems. Steady advances in computation and AAA modeling offer ever more powerful tools for programming artificial worlds. By executing these models on a computer we gain a double advantage: (i) An experimental format allowing free exploration of system dynamics, with complete control of all conditions; and (ii) an opportunity to check the various unfolding behaviors for plausibility, a kind of "reality check." Whether or not agents in such worlds behave in an optimal manner, the very act of contemplating such systems will lead to important questions and answers.

AMERICAN ECONOMIC ASSOCIATION

**PROCEEDINGS
OF THE
HUNDRED AND THIRD
ANNUAL
MEETING**

**WASHINGTON, D.C.
DECEMBER 28-30, 1990**

Minutes of the Annual Meeting Washington, D.C. December 29, 1990

The one hundred and third annual meeting of the American Economic Association was called to order by President Gerard Debreu at 5:55 P.M., December 29, 1990, in the Ballroom of the Sheraton Washington Hotel, Washington, D.C. He began the meeting by reading the items of business on the agenda and the order of business.

The first item to be considered was the minutes of the last annual meeting as published in the *Papers and Proceedings* issue of the *American Economic Review* (May 1990, pp. 453–54). It was moved and seconded to approve the minutes as published. The motion passed without discussion.

The next items considered were the reports of the Secretary (C. Elton Hinshaw), Treasurer (Hinshaw), Editor of the *American Economic Review* (Orley Ashenfelter), Editor of the *Journal of Economic Literature* (John Pencavel), Co-editor of the *Journal of Economic Perspectives* (Carl Shapiro) and Director of *Job Openings for Economists* (Hinshaw). Each discussed his written report (published elsewhere in this issue) which was available to the members prior to the meeting. After the Secretary's report, James Angel asked him what was the probable impact on hotel room rates of moving the annual meeting dates from December 28–30 to the first week in January. Hinshaw responded that there probably would be some increase because a few more conventions and trade shows met during January—competition for hotel space was somewhat heavier. The December period was a notoriously slack time for the hotel industry. However, the Secretary did inform the assembly that single room rates in New Orleans (1992) would be \$60 and in Anaheim (1993), \$63. Carl Lundgren questioned the Secretary about the availability of the agenda prior to the business meeting. He wondered if the Secretary deliberately made it difficult to obtain a copy in order to discourage attendance. Hinshaw responded

that the agenda was made available during the recess between the Presidential Address and the business meeting, and at the AEA booth in the registration area from the beginning of the annual meetings on December 27th. The Executive Committee would be delighted if more members attended the business meeting. (The Secretary notes that just prior to the President's address, the Chair always reminds the audience that the business meeting will follow the address, informs them that the agenda will be available during the recess period, and encourages them to stay for the meeting. The Chair repeats this message again immediately after the address and prior to the recess.) Lundgren stated that no one at the registration site was able to tell him where copies of the business agenda might be obtained prior to the presidential address and that the business agenda was not made available at the business meeting site until after nearly all the attendees at the presidential address had already left.

Ashenfelter reported that the *AER* would probably move to double-blind refereeing—the author does not know who the referee is, the referee is not informed who the author is. He had been testing for the impact of double-blind refereeing on the editorial process at the *Review* by randomly assigning part of the submissions to a double-blind refereeing process. The experiment is completed and a report of the results will be available in 1991. Evidence indicated that the rejection rate of papers that went through the double-blind process was significantly higher than that of the single-blind process (referee knows who the author is but not vice versa). Kenneth Arrow asked if the *AER* had not used double-blind refereeing in the past. Ashenfelter responded that George Borts had used it, but that Robert Clower had abandoned it. Ashenfelter stated that the *AER*'s Board of Editors had voted to adopt such a process.

It was widely perceived to be a fairer system.

Brian Horrigan inquired about publishing one or more of the journals in an electronic format. Pencavel responded that the bibliographic section of the *JEL* was now available in electronic form, on-line through DI-ALOG and on compact disc (CD-ROM) from SilverPlatter Information, Inc. He was not aware of any plans to extend electronic publishing to other AEA journals.

Following the completion of the above listed reports, the Chair called for other business to come before the assembly. Carl Lundgren moved the following resolution, which had been submitted in writing prior to the meeting:

*Resolution to Democratize the
Selection of A.E.A. Officers*

The current wording of Article IV, Section 2, of the Bylaws of the American Economic Association shall be deleted and amended to read as follows:

"Section 2. At least 60 days before the annual meeting the President-elect of the Association shall appoint a Nominating Committee, this Committee to consist of a past officer as non-voting Chairman and not less than seven other randomly selected members of the Association. Members of the Nominating Committee must agree to be present at the meeting of the Nominating Committee, which shall take place one day prior to the main activities of the annual convention, and in the same general place. The President-elect shall send out a sufficient number of invitations to members of the Association, each member having an equal chance of being randomly selected for the invitation, to ensure that at least seven members of the Association agree to serve on the Nominating Committee.

The Nominating Committee shall present to the Executive Committee one nomination for President-elect, two nominations for Vice-President, and two nominations for elected member of the Executive Committee. The Nominating Committee shall also have power to recommend removal or cen-

sure of any elected or appointed officer or employee of the Association. After the Nominating Committee has presented its nominations, the Executive Committee shall decide upon one additional nomination for President-elect, two additional nominations for Vice-President, and two additional nominations for elected member of the Executive Committee.

The nominations of elected officers by the two Committees shall be presented to the members at the annual meeting for discussion and nonbinding vote. If the members present are dissatisfied with the nominees presented, they may by majority vote choose to consider additional nominees. If they so choose to consider additional nominees, they shall be entitled to place on the mail ballots up to one additional nominee for President-elect, up to two additional nominees for Vice-President, and up to two additional nominees for elected member of the Executive Committee.

The actual election of officers by the membership shall take place by mail ballot conducted by the Secretary each year. The ballot shall list all candidates alphabetically, with indications of how many votes each candidate received in the nonbinding vote and which of the two Committees (or the annual meeting) made the nomination. The Secretary shall mail the ballots as soon as practical within six weeks after the annual meeting. The Secretary shall also set a deadline for receipt of ballots, not less than four weeks after the mailing and not more than twelve weeks after the annual meeting. The candidates with the highest number of votes for the various offices shall be elected. The results of the election shall be certified and announced by the Secretary in the *American Economic Review* and at the next annual meeting.

During each mail balloting, the members shall be solicited concerning their suggestions for future nominees to the offices of the Association. The Secretary shall prepare for the Nominating Committee and the Executive Committee a list of all the names suggested, and the number of members making the suggestion, omitting only

such names as are not members of the Association. Also for their use, the Secretary shall solicit from each member whose nomination was suggested by any member, issue and resume information concerning his/her possible candidacy, except that if more than thirty persons have been suggested for any one office, the Secretary may limit these solicitations to not less than thirty persons who have been suggested by the largest number of members."

The Executive Committee is hereby directed by the members assembled to approve the above amendment and to submit it by mail ballot to the members at large.

The Chair asked if anyone in the assembly wished to have Lundgren read the resolution. No one did. The Chair asked if there was a second to the motion. There was not. Lundgren stated that the resolution had already been seconded in writing by Edwin G. Olson, thirty days in advance of the meeting. The Chair ruled that the resolution could only be seconded by someone who was present at the meeting. The motion died on the floor for lack of a second.

The Chair again called for other business. He recognized Lundgren, who moved the following resolution which had been submitted in writing prior to the meeting:

*Resolution to Require Discussion of
Amendment to the Bylaws*

Article VI of the Bylaws which currently reads, "Amendments, after having been approved by a majority of the Executive Committee, may be adopted by a majority of votes cast in a mail ballot," shall be deleted in its entirety.

Article V of the Bylaws shall be amended to insert the following sentences: "Proposed amendments which have been approved by a majority of the members at an annual meeting may be adopted by a majority of votes cast in a mail ballot. Proposed amendments which have been approved by a majority of the Executive Committee may be adopted by a majority of votes cast in a mail ballot, provided that a

resolution concerning the amendment was discussed and voted on by the members at either of the two preceding annual meetings."

The above sentences shall be inserted just before the last sentence of Article V which currently reads: "Mail ballots shall be accompanied by (1) a brief statement by the sponsor or sponsors in support of the resolution, (2) a brief statement of the views of the Executive Committee and, if the Committee favors or takes no position on the resolution, (3) a brief statement by a person or persons whom the Committee designates to represent opposing views."

The Executive Committee is hereby directed by the members assembled to approve the above amendment and to submit it by mail ballot to the members at large.

The Chair asked if anyone wished to have the resolution read. No one so indicated. The Chair asked if there was a second to the motion. There was no second from the floor. The motion died.

The Chair asked if there was other business to come before the assembly. He recognized Lundgren, who moved the following resolution which had been submitted in writing prior to the meeting:

*Resolution to Rescind an Unauthorized
Resolution of the March 1974
Executive Committee Meeting*

The resolution of the March 8, 1974 meeting of the Executive Committee (*AER*, May 1975, p. 449), which purports to impose restrictions on what resolutions may be considered by the members at their annual meeting, is hereby rescinded. This resolution is rescinded because (a) the Executive Committee is not authorized by either the Charter or the Bylaws to impose restrictions on what resolutions the members may properly consider, and (b) a general resolution of this nature is ill-advised, since it fails to allow for legitimate exceptions to the proposed restrictions.

It is recommended for good order that members who know at least 60

days in advance that they would like to bring a resolution before the annual meeting should submit their resolution in writing to the Secretary at least 30 days in advance of the annual meeting. It is recommended (but not required) that the annual meetings refuse to consider surprise resolutions that could have been written up at least 60 days in advance of the meeting.

If the Secretary receives a copy of any proposed resolution which has been proposed and seconded by members of the Association, both being members in good standing, the Secretary shall immediately acknowledge receipt of the resolution and shall immediately submit copies to both the President and Counsel. Within 14 days of receiving the text of the resolution, both the President and the Counsel shall state in writing their opinions concerning whether the resolution should be considered in order or out of order and, if out of order, the reasons why. If the resolution is stated to be out of order, the sponsors shall be invited to present counter-arguments before the Executive Committee, if the sponsor(s) so choose.

If a written resolution has been properly proposed and seconded and submitted to the Secretary at least 30 days in advance of the annual meeting, the Secretary shall reproduce the proposed resolution and make copies available at least one hour in advance of the annual business meeting. Additionally, the Secretary shall do at least one of the following: (a) Distribute copies of the proposed resolution to the membership upon registration at the annual convention, or (b) post copies of the resolution in conspicuous locations prior to registration and leave posted until the annual business meeting is adjourned.

The Chair inquired if anyone wished to have the resolution read. John Roemer asked that he be given one minute to read the resolution for himself. The Chair granted one minute of reading time to the assembly. After the minute had passed, the Chair asked if there was a second to

Lundgren's motion. Roemer seconded it. Lundgren was again granted the floor. He favored the motion for reasons given in the resolution and expanded upon them. He noted that there is no *quid pro quo* in the present procedure. Members have to propose motions 30 days prior to the meeting, but the officers of the Association can rule them out of order without prior notice to the proposer of the motion. An "out of order" ruling without prior notification is unfair. It deprives one of the freedom of speech. It indicates that the person is not worth listening to. Requiring prior notice of such a ruling seemed reasonable. He recalled that a previous resolution of his had been ruled out of order by the Executive Committee in a meeting to which he was not allowed to attend. He thought that to be unfair. He further stated that the Secretary had not acknowledged receipt of his resolutions until December 18th, indicating that he did not think that soon enough. He ended by indicating that sufficient information about the agenda was not made available and this explained the poor attendance at the business meeting. He expressed some doubt that the resolutions were available when and where the Secretary had earlier in the meeting stated them to be. The Secretary apologized to Lundgren for the late acknowledgement of his resolutions. He stated that it was his practice to inform first those who had submitted resolutions that were not in good order. He apparently had implicitly been assuming that proposers of resolutions would assume that "no news was good news," that is, the resolutions had been received. The Secretary added, however, that a resolution was not necessary to get him to send an acknowledgment. He would mend his ways. Roemer asked about the restrictions imposed on resolutions that were referred to in Lundgren's resolution. The Secretary responded that the restriction was a time restriction—resolutions had to be received by the Secretary 30 days prior to the annual meeting so that they could be duplicated in time to distribute at the meetings. Robert Eisner added that not all resolutions, even if submitted properly, would necessarily be in order. Some resolu-

tions were outside the stated purposes of the Association and in conflict with the charter and bylaws. Such resolutions would be ruled "out of order" by the Chair. The President, not the Executive Committee, makes such a ruling. He, Eisner, had been President when Lundgren submitted his first resolution. As Chair of the meeting, he had ruled it out of order. (The interested reader is referred to the minutes of the 1988 annual business meeting, *Papers and Proceed-*

ings issue of the *American Economic Review*, May 1989, p. 391.) The Chair then called for the vote. The motion failed with only one person voting in favor.

There being no other business before the assembly, Debreu introduced the incoming President, Thomas Schelling, who adjourned the meeting at 6:30 P.M.

Respectfully submitted,
C. ELTON HINSHAW, *Secretary*

Minutes of the Executive Committee Meetings

Minutes of the Meeting of the Executive Committee in Washington, D.C., March 23, 1990.

The first meeting of the 1990 Executive Committee was called to order at 10:00 A.M., March 23, 1990, in the Congressional Room of the Sheraton Washington Hotel in Washington, D.C. Members present were Gerard Debreu (presiding), George Akerlof, Orley Ashenfelter, Gregory Chow, Rudiger Dornbusch, Robert Eisner, Stanley Fischer, C. Elton Hinshaw, Allan Meltzer, John Pencavel, Isabel Sawhill, Thomas Schelling, and Joseph Stiglitz. Present as Counsel was Leo Raskind. Present for a part of the meeting were members of the 1990 Nominating Committee: Gary Becker, Duncan Foley, Edward Lazear, Frank Levy, John Shoven, and Janet Yellen.

Minutes. The minutes of the meeting of December 27, 1989, were approved as written and circulated prior to the March meeting.

Report of the Secretary (Hinshaw). The 1989 meeting in Atlanta attracted 6,627 registrants, a record number for a meeting away from the East Coast. The previous high was 6,384 at the 1987 Chicago meeting. Forty-one other associations, societies, and organizations met with us, 428 scholarly sessions were organized, and 114 events (lunches, cocktail parties, committee meetings, etc.) scheduled.

The Secretary reported that he had investigated the possibility of meeting in San Francisco and Chicago in 1993. Both cities reported conflicts with already booked conventions. The largest hotel in Los Angeles is owned by Portman Properties. This eliminates L.A. as a potential site for the time being. Both Seattle and San Diego would require the use of a convention center and shuttle services, things we try to avoid. The Secretary noted that the growth in attendance was beginning to present problems for site selection. Fewer cities had the hotel facilities required for the meetings. Most cities would now require the use of a convention center or shuttling or both. The discussion indicated that, in general, we should continue to try to avoid both conven-

tion centers and busing in city selection. It was VOTED to authorize the Secretary to negotiate contracts with the hotels in Anaheim, California for the 1993 meeting.

Since the option of *not* receiving one of the journals with a \$6 reduction in dues has become available, some 7,583 persons have renewed their memberships or joined. Ninety-one percent (91%) elected to receive all three journals; 2% elected not to receive the *American Economic Review*; 3%, the *Journal of Economic Literature*; and 3.5% the *Journal of Economic Perspectives*. Five people seem to have elected not to receive any of the three.

After a discussion of the proposal submitted by Trans National Financial Services, it was VOTED not to establish an affinity credit card program. Concern was expressed that the Association would be viewed as endorsing a specific credit card by entering into such a contract. The Association did not wish to do that.

It was VOTED to submit an amendment to Article V, Section 2 of the bylaws to a vote of the members. The proposed amended bylaw would read as follows:

A resolution adopted at an annual meeting in which less than five percent of the membership of the Association has voted thereon shall be submitted to a vote by mail ballot no later than the ballot for officers if a majority of the Executive Committee determines that, because of the nature or consequences of the resolution, all members should have the opportunity to participate in the final decision.

Dan Newlon, of the National Science Foundation, had inquired if the Association had an interest in developing an annual "directory" of *all* academic economists, not just AEA members. The NSF would find such a directory of great value. Newlon had generated a couple of proposals from others, which had been sent to the Secretary, to develop such a data base, and he would like the AEA's participation. The existing proposals were not sufficiently well-defined

to reach a judgment, but it was decided that the subject should be pursued by the Secretary.

Report of the Editor of the American Economic Review (Ashenfelter). It was VOTED to approve the Editor's recommendation of reappointment of the following persons to the Board of Editors: George Akerlof, Jo Anna Gray, John F. Kennan, and Richard Roll. With the same vote, his recommendation of John Campbell, Robert Hodrick, and Hal Varian as new members was also approved. In response to a question, Ashenfelter stated that the size of the Board had grown in number, primarily because each of the co-editors needed members in their specific areas. Board members were used heavily as referees. He also reported that the report on double-blind refereeing might be finished this summer; he expected to give the results at the next meeting.

Report of the Editor of the Journal of Economic Literature (Pencavel). Pencavel reported that the Association had entered into a contract with SilverPlatter to put the bibliographic section of the *JEL* on a compact disk (CD-ROM). The *JEL* will provide the data and help market the disk; SilverPlatter will develop the software, produce the disks, and also market the product. The new product does not replace the on-line data base with DIALOG; it simply makes the same data base available in a different electronic form. There was some concern that the pricing structure effectively eliminated the individual user. It was suggested that it might be feasible to make the disk available with a year's lag at a price that individuals could afford. He further reported that he hoped to have the new classification scheme in place by this summer. It is currently being reviewed for final revisions.

Report of the Editor of the Journal of Economic Perspectives (Stiglitz). Stiglitz reported that he was in the process of arranging symposia on several topics, some of which are Third-World Debt, Bubbles, The Role of the State in Development, Intellectual Property Rights, and The Economic Status of Blacks.

Report of the Director of Job Openings of Economists (Hinshaw). Hinshaw reported

that he had received a letter from a member, Carl Lundgren, proposing a change in the subscription policy to *JOE*. Currently only AEA members may subscribe. Lundgren proposes that nonmembers be allowed to subscribe at a rate that is not higher than average cost. The Director agreed with the proposal and recommended that a new category of subscriber—Institutions and Nonmembers—be established and that the rate be \$25 (plus postage if outside the United States). It was VOTED to accept the Director's recommendation.

The 1990 Program (Schelling). Schelling reported that currently he had organized 51 sessions for the meetings, 22 of which are scheduled to be published in the *Papers and Proceedings* issue of the *AER*. Titles of some of the sessions are Post-Communist Economic Transition, Rumania and Bulgaria, Hungary and Poland, Czechoslovakia, Yugoslavia, and East German, China, East and West Europe in 1992, Tax Reform, Learning, Space, The Nonrational in Decisions, Greenhouse Warming, Altruism, Illicit Drugs, and Conflict.

After Schelling completed his description of the program for the coming year, the discussion turned to the issue of "openness" of the program. There was some suggestion that perhaps the selection of papers to be published in the *Papers and Proceedings* might be made more open if papers had to be submitted prior to the meetings and without the "guarantee" of publication. If publication was not automatic, better papers may result. Some thought that the distinctive nature of the *Papers and Proceedings*, the short deadlines involved, and the prerogatives of the Presidents to have the program reflect their interest made "competitive" publication less feasible and less desirable. No action was taken.

Report of the Nominating Committee (Becker). Becker, who chaired the Committee, reported the following nominations for the indicated offices: for Vice-President—Henry J. Aaron, Claudia D. Goldin, Robert E. Hall, and Daniel McFadden; for the Executive Committee—Michael J. Piore, T. N. Srinivasan, Martin L. Weitzman, and Gavin Wright. The Nominating Committee and the Executive Committee, acting together as an

electoral college, nominated William Vickrey as President-elect and elected Victor Fuchs and Merton Miller as Distinguished Fellows.

Report of the Treasurer (Hinshaw). Audited financial statements for 1989 were distributed prior to the meeting. The statements show an operating deficit of \$450 thousand, up from \$398 thousand in 1988. After taking into account investment income recognized of \$297 thousand, the overall deficit was \$153 thousand. The operating loss was \$21 thousand smaller than budgeted and investment income was \$32 thousand larger than the \$265 thousand budgeted. The overall deficit was \$53 thousand less than anticipated. Cash and investments increased from \$5.9 million in 1988 to \$6.4 million at the end of 1989.

The Budget Committee had met that morning and made the following general policy recommendation: Increase membership dues annually at the same rate as the increase in the Consumer Price Index until such time as the ratio of net worth to annual expenditures equals one. This policy presupposes that such increases will continue to result in operating deficits and that such deficits should be tolerated until the Net Worth/Annual Expenditures ratio decreases to one. If the ratio rises much above where it now is, say to two, the policy should be reconsidered. This could happen if there was a significant increase in the value of the Association's portfolio of investments.

In keeping with this general policy, the Budget Committee recommended that 1991 dues be increased by the increase in the CPI from June 1989 to June 1990. It was VOTED to increase dues by the recommended amount. It was understood that the increase would be rounded to the nearest dime and that the Treasurer could, if necessary because of time constraints for printing renewal notices, etc., change the dates for calculating the change in the CPI.

Other Business. It was VOTED to reappoint Ashenfelter to a third term as editor of the *American Economic Review*. It was VOTED to reappoint Pencavel to a third term as editor of the *Journal of Economic Literature*. Both terms would end December

31, 1994. There followed a discussion of the desirability of establishing a more systematic procedure for reviewing the performance of the editors and the quality of the journals. Both editors thought such a procedure would be useful. Although there seemed to be a consensus that the suggestion was a good one, no specific action was taken.

An *Ad Hoc* Committee of three (Meltzer, Akerlof, and Dornbusch) was appointed to arrange three or four sessions for the 1990 meetings devoted to discussing (teaching) some of the more recent and useful research techniques that have been developed, a kind of "continuing education" section of the AEA program. It was noted that there is a substantial lag between the time new innovations are developed and their appearance in textbooks. These sessions would substantially reduce that lag. They might best be described as lectures on chapters that might appear in a graduate textbook with an accompanying reading list.

The final item of discussion was techniques and strategies for increasing membership in the Association. The Secretary noted that he had instituted an exchange of ads with two Japanese journals but had taken no further action. Several possibilities were put forward—ads in the *Economist*, the *New York Times*, and the *Wall St. Journal*, buying various mailing lists and doing a direct mailing, etc. Ashenfelter volunteered to investigate the cost of obtaining the mailing list of the *Economist*. The Secretary will inquire of other social science societies what procedures they use to seek new members.

The meeting was adjourned.

Minutes of the Meeting of the Executive Committee in Washington, D.C., December 27, 1990.

The second meeting of the 1990 Executive Committee was called to order at 10:00 A.M., December 27, 1990, in the Congressional Room of the Sheraton Washington Hotel in Washington, D.C. Members present were Gerard Debreu (presiding), George Akerlof, Orley Ashenfelter, Gregory Chow, Rudiger Dornbusch, Robert Eisner, Stanley Fischer, C. Elton Hinshaw, Allan Meltzer, John Pencavel, Susan Rose-

Ackerman, Thomas Schelling, and Lawrence Summers. Present as guests were Henry Aaron, Claudia Goldin, Michael Piore, Carl Shapiro, and William Vickrey. Present for the purpose of giving reports were Nancy Gordon, Lee Hansen, Anne Krueger, and Margaret Simms. Present as Counsel was Leo Raskind.

Debreu opened the meeting by greeting the guests and reviewing the agenda. The first item of business was the approval of the minutes of the March 23, 1990, meeting. These were approved as written.

Report of the Secretary (Hinshaw). The Secretary added his welcome to the new members of the 1991 Executive Committee and thanked those of the present Committee whose terms were expiring—Akerlof, Dornbusch, Eisner, Meltzer, and Sawhill. He then informed the group that the next annual meeting would be held in New Orleans on January 3–5, 1992, and the 1993 meeting in Anaheim, January 5–7. The Secretary said that cities currently under consideration for 1994 were Boston, Denver, and New York. He, once again, reviewed some of the problems being generated by the growth in the number of sessions, events, and attendance. This growth, combined with the reluctance to use convention centers, caused him to recommend that the meetings be extended to three full days. Sessions can no longer be accommodated within a two and a half day framework. After discussing other options such as having another period for sessions that would begin about 4:00 or 4:30 P.M., it was agreed that the meetings would be extended to include the afternoon of the third day. He reported that the “telephone directory” would be published during the fourth quarter of 1991. It would contain name, full address (the one to which the journals are sent), office phone and fax numbers, but no biographical information. It will be sent to members free of charge. It was VOTED to authorize a charge of up to but no more than \$10.00 to non-members and subscribers for the telephone book.

Since October of last year, members have had the option of not receiving one of the three journals and having their dues re-

duced by \$6.00. Since then some 21,000 persons have renewed their memberships or joined the Association. Of these, some 1,985 elected not to receive one of the journals. Four hundred seventy-one (471) elected not to receive the *AER*; 716, the *JEL*; and 787, the *JEP*. Eleven people have chosen to receive none of the three.

The Secretary had recently received an order for mailing labels of the membership for the purpose of sending a fund-raising appeal for University Scholarships for South African Students, Inc., which claims to be a nonprofit, tax-exempt organization. He declined to sell the membership list for this purpose. He is currently authorized to sell the list for commercial purposes. As far as he could determine, the list had never been sold for the purpose of soliciting contributions to worthy causes. The list is currently sold primarily to publishers. If a request is received that is not a “standard” one, the Secretary makes an *ad hoc* decision based on his judgment of the appeal of the proposed mailing to the membership. He asked for advice or instruction about what the policy should be. It was VOTED to authorize the Secretary to sell the membership list to all who requested it for a period of two years. The experiment would then be evaluated to determine if a change in the policy was needed. The Secretary understood that some modicum of inquiry might be undertaken to determine the “legitimacy” of the potential purchaser.

Report of the Editor of the American Economic Review (Ashenfelter). Ashenfelter briefly reviewed his written report which is published elsewhere in this issue and circulated to the Committee prior to the meeting. It was VOTED to approve his recommendation to reappoint James E. Anderson, appoint Kyle W. Bagwell, D. John Roberts, and Suzanne A. Scotchmer, and extend by one year the term of David Sappington as members of the *AER* Board of Editors.

He also reported that the experiment on double-blind refereeing which had been underway for about two years was over and that the final report would be published sometime in 1991. The one definite result to

be reported now was that double-blind refereeing makes a statistically significant difference in the acceptance rate for publication—the double-blind acceptance rate is only about 70 percent of the single-blind rate. As a result of this finding, Ashenfelter thought that the *AER* would move to the double-blind refereeing process. The Board of Editors was scheduled to discuss the issue later at these meetings.

Report of the Editor of the Journal of Economic Literature (Pencavel). Pencavel highlighted some of the items presented in his written report which was circulated prior to the meeting and is published elsewhere in this issue. It was VOTED to approve his recommendation to appoint Sherman Robinson to a three-year term on the Board of Editors. He announced that the new classification scheme which had been under consideration for the past two years would be introduced during 1991. Further, the Economic Literature Index is now available in the form of compact discs through Silver-Platter Information, Inc. as well as on-line through DIALOG. Initial sales of the disc are encouraging. Currently under review are the criteria for selecting journals to be included in the bibliographic sections of the *JEL*.

Report of the Editor of the Journal of Economic Perspectives (Shapiro). In the absence of Joe Stiglitz, Co-editor Shapiro reviewed the written report which is published elsewhere in this issue. Two new features have been added: "Retrospectives" and "Policy Watch." These replace, in part, "Puzzles" and "Anomalies." Some of the symposia to be published in 1991 are "Intellectual Property," "Trade Liberalization," and "Socialist Economies." It was VOTED to approve the recommendation to appoint Peter Murrell and Gene Grossman to the Board of Editors for terms of three years.

Report of the Director of Job Openings for Economists (Hinshaw). Hinshaw reviewed his written report which is published elsewhere in this issue. He then called the Committee's attention to a special situation that had arisen during the past year. An AEA member, Pinaki Sankar Bose, had

written him to complain about the hiring procedures of Concordia University (Montreal, Canada). The barest facts seem to be that Bose was offered in writing a three-year, tenure-track position by the Chair of the Economics Department. Bose accepted and notified his other employment options that he had done so. Subsequently, the Dean of Concordia unilaterally changed the official offer to a one-year, nontenure track appointment for reasons that did not entail the qualifications of Bose. Bose wrote the Secretary to complain. The Secretary wrote (May 17, 1990) the Rector of Concordia, stating the allegations of Bose and asking the Rector to review the facts, judge the validity of the allegations, and ascertain what responsibility Concordia had to Bose.

In October, Concordia submitted an ad for *JOE*. As Director of *JOE*, Hinshaw wrote (October 19, 1990) the Chair of the Economics Department informing him that he had received no response from the University concerning Bose's allegations and informed him that if Concordia wished to use the services of the Association to help recruit faculty members, the Association needed assurance that its help would be used appropriately and responsibly. Hinshaw said he would not publish the ad without a response to his inquiry of May 17th.

The Rector responded in a letter dated October 24, 1990, in which, in part, he gave his assurances that such an incident would not occur again and steps had been taken to prevent such an event in the future. Hinshaw's reading of his response led him to conclude that (1) Bose's allegations concerning his dealings with Concordia University were accepted as true by the University, (2) Bose was the victim of an internal misunderstanding within the University, (3) no official action was taken by the University from the time of Hinshaw's first inquiry on May 17th to his second of October 19th, and (4) the Rector had concluded to do nothing to remedy the damage done Bose except send him a formal letter of apology, dated October 24, 1990. Based on his understanding of all that had transpired, Hinshaw decided to deny publication of Con-

cordia's ad in the December issue of *JOE* and bring the situation to the Executive Committee's attention to determine what it might wish to do.

It was VOTED to affirm the Director's decision to deny Concordia University the privilege of advertising in the December issue of *JOE* and to extend the prohibition to August 1, 1991.

The Committee then discussed if a "warning" to job applicants should be published in *JOE* to alert them to the sometimes subtle distinction made by some universities between "informal" offers by Chairs and "formal" offers by Deans since the Association takes very seriously the responsibility of universities to make offers in good faith, to be careful about who makes commitments for it, and to live by commitments made on its behalf. No action was taken.

Report of the Committee on the Status of Women in the Economics Profession (Gordon). Gordon commented on her written report which had been circulated to the Executive Committee prior to the meeting and is published elsewhere in this issue. The discussion that followed concerned the slow progress of women through the professorial ranks. Despite the substantial growth of women in the profession during the past decade, this increase is not appearing as yet in the senior ranks. The proportion of assistant and associate professors who were women approximately tripled between 1974 and 1989, rising from 8 to 20 percent and from 3 to 9 percent respectively; the proportion of full professors who were women grew only from about 2 to 3 percent.

Report of the 1991 AEA Program Chair (Vickrey). Vickrey, President-elect for 1991, reported that proposals for sessions and abstracts of papers had begun to flow into his office. He had not yet settled on a focus for the program.

Report on the Status of Minorities in the Economics Profession (Simms). Simms is the new Chair of the Committee, having taken over from Ron Oaxaca. She reported that the Committee had recommended that the Summer Program be awarded to Stanford

University for a period of three years with an option to renew for two more. Tom Macurdy will be the Director. The Committee currently has funds from the Ford Foundation sufficient to operate the program for another three years. A written report is published elsewhere in this issue. It was suggested that the Committee consider giving higher stipends to fewer participants.

Report of the Commission on Graduate Education (Krueger and Hansen). Krueger reported that the Commission had finished its work and would present its recommendations at a session at the current meetings. The final report along with a background paper by Hansen would be available. Current discussions were underway with the Editors of the AEA journals about which journal would be the most appropriate place to publish the Commission's findings. Commercial publishers were available to publish the Commission's work in monograph form. The Commission recommended that the AEA hold the copyright and receive any royalties. It was VOTED to accept any royalties. It was understood that Hansen, in consultation with Raskind, would negotiate the contract with prospective publishers. It was also understood that the Treasurer would keep track of the amount of royalties received from this source as a potential reminder that a follow-up study might be undertaken in five or so years. It was VOTED to thank and commend the Commission for its work.

Other Business. It was VOTED to commend the *Ad Hoc* Committee (Meltzer, Akerlof, and Dornbusch) that arranged the "continuing education" lectures for these meetings and to reappoint them and ask them to do it again for the 1992 meetings.

During the course of the discussion of three resolutions by Carl Lundgren and one by Suresh Deman, it was VOTED to endorse President Debreu's decision not to invite Lundgren to attend the meeting of the Executive Committee. It was also VOTED to submit to the membership an amendment to the bylaws that would make resolutions passed at the annual AEA business meeting with fewer than half of one

percent of the membership present and voting advisory only. This latter motion was passed following a long discussion lamenting the poor attendance at the business meetings. With some regularity, resolutions are passed with fewer than 50 members voting. Suggestions were offered about how to increase attendance (for example, change the time). The Secretary reminded the group that the business meeting was in its current time slot because attendance had been worse when it was held separately from the Presidential Address and when the Presidential Address had been held at 8:00 P.M. It was also suggested that more signatures be required on resolutions before they could be considered. During a discussion of the nominating process, considerable support was expressed for some review, examination, and possible changes in the procedures. It was understood that the Executive Committee wished to reexamine the nominating process, perhaps by a committee ap-

pointed for that purpose. Ultimately, the only actions taken were those reported above.

Finally, the Committee considered a suggestion from a member concerning the establishment of a new award to honor that economist or group of economists who had contributed most to the analysis and discussion of public policy issues. The member had suggested the award be named after Joe Pechman. The Committee, although apparently sympathetic with the idea, deferred any action.

Report of the Treasurer (Hinshaw). Hinshaw reviewed his report which is published elsewhere in this issue. It was VOTED to approve the 1991 budget as submitted.

There being no further business, the meeting adjourned at 5:50 P.M.

Respectfully submitted,
C. ELTON HINSHAW, *Secretary*

Report of the Secretary for 1990

Telephone Directory. The American Economic Association will publish a "telephone directory" of members in late 1991. It will be generated from the journal mailing list and will include the name, address, and telephone/fax numbers of AEA members who have active memberships as of June 1991. A space is now provided on both the membership application and renewal notice for correcting telephone numbers and adding a fax number.

Annual Meetings. The next annual meeting will be held in New Orleans, January 3-5, 1992. Placement Service will open for business one day earlier (January 2) than the meetings. There is no meeting in 1991.

Elections. In accordance with the bylaws on election procedures, I hereby certify the results of the recent balloting and report the actions of the Nominating Committee and the Electoral College.

The Nominating Committee, consisting of Gary S. Becker, Chair, Duncan K. Foley, Edward P. Lazear, Frank S. Levy, John B. Shoven, Peter Temin, and Janet L. Yellen submitted the nominations for Vice-Presidents and members of the Executive Committee. The Electoral College, consisting of the Nominating Committee and Executive Committee meeting together, selected the nominee for President-elect. No petitions were received nominating additional candidates.

President-elect
William Vickrey

<i>Vice-President</i>	<i>Executive Committee</i>
Henry J. Aaron	Michael J. Piore
Claudia D. Goldin	T. N. Srinivasan
Robert E. Hall	Martin L. Weitzman
Daniel McFadden	Gavin Wright

The Secretary prepared biographical sketches of the candidates and distributed ballots last summer. On the basis of the canvass of ballots, I certify that the following persons have been duly elected to the

respective offices:

President-elect (for a term of one year)
William Vickrey
Vice-Presidents (for a term of one year)
Henry J. Aaron
Claudia D. Goldin
Executive Committee (for a term of three years)
Michael J. Piore
Gavin Wright

In addition, I have the following information:

Number of legal ballots	5,034
Number of invalid envelopes	244
Number of envelopes received after October 1	29
Number of envelopes returned	5,307

The proposed amendment to the bylaws was adopted; the bylaws as amended now read:

Article V, Section 2

2. A resolution adopted at an annual meeting in which less than five percent of the membership of the Association has voted thereon shall be submitted to a vote by mail ballot no later than the ballot for officers if a majority of the Executive Committee determines that, because of the nature or consequences of the resolution, all members should have the opportunity to participate in the final decision.

Membership. The total number of members and subscribers is shown in Table 1.

TABLE 1—MEMBERS AND SUBSCRIBERS
(End of Year)

	1988	1989	1990
Class of Membership			
Annual	17,410	18,172	17,863
Junior	1,939	2,170	2,533
Life	353	338	318
Honorary	33	33	33

Subscribers	5,793	5,736	5,785
Total Members and Subscribers	26,440	27,306	27,363

The total has fluctuated between 25,000 and 27,500 since 1975. This year it reached an all-time high of 27,363, an increase of 57 over last year.

National Registry. The National Registry for Economists continues to be operated on a year-round basis by the Illinois State Employment Service. Economists looking for jobs and employers are urged to register. This is a placement service that maintains the anonymity of employers. The Association is indebted to the Registry for assistance and supervision at the employment service provided at the annual meetings. Employers are reminded of the Association's bimonthly publication, *Job Openings for Economists*, and their professional obligation to list their job openings.

Permission to Reprint and Translate. Official permission to quote from, reprint, or translate and reprint articles from the *American Economic Review*, *Journal of Economic Literature* and the *Journal of Economic Perspectives* totaled 602 in 1990, compared to 696 in 1989. Upon receipt of a request for permission to reprint an article, the publisher or editor making the request is instructed to obtain the author's permission in writing and send a copy to the Secretary as a condition for official permission. The Association suggests that authors charge a fee of \$150, but they may charge some other amount, enter into a royalty arrangement, waive the fee, or refuse permission altogether.

Staff. The staff in the Secretary's office is unusually loyal, gracious, and efficient. I am indebted to them as is the Association. They are Mary Winer, Kim Adair, Norma Ayres, Dana Coleman, Sherry Davis, Marlene Hall, Dana Jackson, and Violet Sikes.

Committees and Representatives. Listed below are those who served the Association during 1990 as members of committees or representatives. The year in parentheses indicates the final year of the term to which they were appointed. On behalf of the Association, I thank them for all their service.

C. ELTON HINSHAW, *Secretary*

Report of the Treasurer for the Year Ending December 31, 1990

The proposed budget for 1991 in Table 1 projects an operating loss of \$637 thousand, investment income of \$252 thousand, and an overall deficit of \$385 thousand. The deficits result primarily from the decision to begin publication of the *Journal of Economic Perspectives* without an increase in real dues. Net worth at the beginning of 1991 is expected to exceed budgeted expenditures by more than a million dollars so drastic action is not required. Another deficit can be accommodated.

Audited statements for 1990 will be published in the June issue of the *American Economic Review*.

I wish to thank Norma Ayres, our accountant, and Mary Winer, the Administrative Director, for their valuable help and patience in assisting me in carrying out the duties of the Treasurer.

C. ELTON HINSHAW, *Treasurer*

Report of the Finance Committee

The Finance Committee of the American Economic Association met at the Chicago Club, Chicago, Illinois, at 11:45 a.m. on December 13, 1990. Present were Richard Peterson, Robert Hamada (members of the Committee), and C. Elton Hinshaw (Chairman of the Committee and Secretary-Treasurer of the Association); Robert McNeill and Harvey Hirschhorn (representing Stein Roe & Farnham, investment counsel for the Association).

In 1987, the Committee reviewed recommendations presented by the AEA Committee on Indexing Association Funds concerning the long-term allocation of the Association's investment assets. As a result of that recommendation and the subsequent deliberation of the Finance Committee, it was agreed that the Association's portfolio be comprised of a combination of the Wells Fargo South Africa Free Index Fund, Stein Roe & Farnham's specialty equity mutual funds, and a bond portion managed by Stein Roe & Farnham.

This restructuring took place at the end of June 1988. The current portfolio includes holdings in the Wells Fargo South Africa Restricted Equity Index B, as well as the International Growth, Special and Stock Funds, which are all managed by Stein Roe & Farnham. The Fixed Income portion of the portfolio is currently invested in short/medium-term U.S. government agency notes

and SRF's intermediate-term taxable funds (Managed Bonds & Governments Plus).

As a result of the aforementioned asset allocation restructuring, the overall performance of the Association's fund now reflects the combined efforts of Wells Fargo and Stein Roe & Farnham.

With respect to the 1990 performance (through December 31) of the Association's portfolio, the total return of the account including cash, bonds, and SRF equity funds was -2.6 percent. Focusing on a longer-term period, over the six years ending with December 1990, the total return for the account was +88.3 percent. In dollars, the total return has been approximately \$2,500,000 over the last six years.

After considering the economic outlook and the composition of the Association's portfolio, the Committee approved a 50-70 percent allocation to equities (including the Wells Fargo Fund). In addition, it was decided that international equity exposure should range from 5 to 15 percent, and the minimum cash equivalent position should be 5 percent. The benchmark for performance is a portfolio consisting of 60 percent equities and 5 percent cash equivalents.

Members can obtain a list of the assets in the portfolio by writing the Treasurer.

C. ELTON HINSHAW, *Chair*

Report of the Editor

American Economic Review

The editorial process has continued to work very smoothly during the past year despite some changes in personnel at the *Review*. Our current submission rate (of nearly 1,000 papers per year) has remained fairly stable at a level we first achieved in the early 1980's.

Editorial Process

As Table 1 indicates, the number of submissions has decreased by about 4 percent over last year. Nevertheless, the chances that a submitted paper will eventually be published have decreased slightly from last year to this year. The fraction of submitted papers that we publish is now at an all time historical low of .11.

Table 2 indicates that we published more articles and fewer shorter papers in the *Review* in 1990 than in 1989, and that the total number of pages published dropped slightly. I and my co-editors have adopted a conscious policy of attempting to increase the number of major substantive articles we publish at the expense of shorter papers, comments, and replies. We had some success at doing so during the last year.

Tables 3 and 4, when compared with the results for last year, indicate there has been a small slowdown in the speed with which we handle manuscripts that are ultimately

rejected. A major cause of the delay in handling manuscripts can be attributed, as I indicated in my Report last year, to the use of referees and to the slowness with which we receive reports. From 1989 to 1990, I

TABLE 1—MANUSCRIPTS SUBMITTED
AND PUBLISHED, 1971–90^a

and my co-editors have again increased our use of the refereeing process. The result has been an increase in the delay with which we handle manuscripts.

Table 5 indicates that there has been some change from last year in the speed with which accepted papers were published in the *Review*. We continued during 1989-90 to build up a backlog of accepted papers, and this naturally led to an increase in the lag between acceptance and publication. Building up our backlog has, on the whole, been desirable, since we had been operating with far too tight a printer's deadline in the last three years. I now feel that our backlog has stabilized and I suspect that this may lead to a shortening of the time between acceptance and publication of articles in the *Review*.

TABLE 3—DISPOSITION OF MANUSCRIPTS,
1989 AND 1990

	July 1, 1988– June 30, 1989	July 1, 1989– June 30, 1990
Manuscripts Received	923	916
Completed Processing	568	526
Accepted	38	26
Rejected	530	500
Currently in Process	355	390

The subject matter distribution of papers published in the *Review* in 1989 and 1990 is contained in Table 6. It remains my impression that the distribution of published papers reflects fairly accurately the distribution of papers submitted.

Finally, as I reported earlier in the year, we have been testing for the impact of double-blind refereeing on the editorial process at the *Review* by randomly assigning part of our submissions to a double-blind refereeing process. This experiment is now complete and a report of its results will be available in mid-1991.

Papers and Proceedings

The twelfth volume of the *Papers and Proceedings* to be prepared by the editorial staff of the *Review* appeared in May 1990. For the last two years this task has been very capably handled by Ronald Oaxaca (University of Arizona) and Wilma St. John. I am deeply indebted to both of them for the difficult work under extraordinarily tight deadlines that they have so capably performed.

Co-Editors and Board of Editors

There was one major change in the editorial personnel at the *Review* in the last year.

December 1990	59	49	107

Claire Comiskey, our production editor, resigned due to ill health. I am deeply grateful for all the help and effort she provided over the three-year period she served as production editor.

David Baldwin, formerly affiliated with the biology journal *Evolution*, has become our new production editor. His knowledge of scientific writing has already proved invaluable and will, I am sure, help us to improve the clarity of scientific discourse in the *Review*.

I edit the *Review* with the assistance of Robert Haveman (University of Wisconsin), Bennett McCallum (Carnegie Mellon University), and Paul Milgrom (Stanford University). I am deeply indebted to them for the conscientious effort they have expended over the last year.

The Board of Editors now consists of twenty-eight members and I am indebted to

judgment, and professional reliability. When possible, we like to select Board members from those economists who have been especially helpful in the outside refereeing process.

Two members of the Board completed their terms during 1990: Maurice Obstfeld and Kenneth Singleton. I am most grateful to them and to the continuing members: George Akerlof, James Anderson, Timothy Bresnahan, John Campbell, Henry Farber, Marjorie Flavin, Robert Flood, Claudia Goldin, Jo Anna Gray, Reuben Gronau, Daniel Hamermesh, Robert Hodrick, Kevin Hoover, Kenneth Judd, John Kagel, John Kennan, Edgar Olsen, John Riley, Richard Roll, Thomas Romer, David Sappington, Robert Smith, Barbara Spencer, Richard Tresch, Hal Varian, Kenneth West, John

Wilson, and Leslie Young. I am also grateful for the assistance of many other associates who make it possible to edit and produce the *Review*. I am indebted to our office manager, Shirley Griesbaum, and our editorial assistants, Sandra Grant and Kathy Simkanich, for the fine work they have continued to perform over the past year. I would also like to thank the co-editors' secretaries: Joan Sample (Robert Haveman's office); Pat Niber (Bennett McCallum's office); Kim Mooney and Deborah Johnston (Paul Milgrom's office).

As always, the published version of this Report contains the list of referees who have volunteered their services during 1989. We extend our deepest appreciation for the time and energy they have devoted to the advancement of our science.

ORLEY ASHENFELTER, *Editor*

Report of the Editor

Journal of Economic Literature

The mission of the *Journal* remains that of helping members of the Association maintain a broad understanding of developments in many branches of economics, and of assisting their work by providing them with a wide range of bibliographic material. These aims are served by articles, book reviews, annotations of new books, listings of the contents of current periodicals, selected abstracts, and listings of recent doctoral dissertations.

The *Journal's* work is divided between two offices. The Pittsburgh office under the direction of Drucilla Ekwurzel is responsible for the bibliographic material including the contents of current periodicals, certain abstracts, and new book annotations. Mary Kay Akerman is an Assistant Editor and Asatoshi Maeshiro is an Editorial Consultant to our Pittsburgh branch. They have been helped further by the work of Patricia Andrews, Elise Braden, Elizabeth Braunstein, and Elizabeth Thornton. I thank them all for their considerable efforts during the past year.

The Pittsburgh office is responsible also for the *Index of Economic Articles* and the *Economic Literature Index*. The latter is

available now not only on line through Dialog Information Services, but also in the form of compact discs through an arrangement with SilverPlatter Information. The EconLit database on disc provides over two decades of journal citations, abstracts of journal articles, book annotations, and dissertation titles. More information on computer access to the *JEL* bibliographic data is contained in each issue of the *Journal*.

Next year we shall be introducing a new Classification System for articles and books. We embarked on a revision of the old system two years ago and, having drawn upon the advice and suggestions of many people, we have been able to devise what we think is a scheme more appropriate to current economics. When we introduce this new Classification System, we shall merge our Subject Index of Articles in Current Periodicals with Selected Abstracts and thereby effect some economies. Though we try to contain the growth in the *Journal's* budget, the relentless expansion in economics publications makes this difficult. Table 1 provides information on the size of the *Journal's* various departments over the past decade.

TABLE 1—*JEL* PAGES BY DEPARTMENT, 1980–90

Year	Articles and Communications	Book Reviews	New Book Annotations	Current Periodicals ^a	General Index	Total
1980	366	294	276	1072	26	2034
1981	342	286	270	1059	23	1980
1982	331	251	300	1069	23	1974
1983	305	239	281	1086	38	1949
1984	354	225	314	1193	37	2123
1985	364	237	299	1306	38	2244
1986	326	250	308	1343	41	2268
1987	345	251	315	1352	40	2303
1988	419	241	318	1240	40	2258
1989	334	251	328	1254	41	2208
1990	323	234	366	1339	44	2306

^aIn 1987, the *Journal of Economic Literature* took over from the *American Economic Review* the responsibility of publishing the list of Doctoral Dissertations in Economics. This item is added to "Current Periodicals" which also includes the Contents of Current Periodicals, the Subject Index of Articles in Current Periodicals, and Selected Abstracts. The figures for 1990 include estimates regarding the December issue.

The Articles and Book Reviews departments of the *Journal* are handled by the Stanford office. During 1990, we published nine major articles, one review article, an exchange concerning the purposes of national income accounts, and 159 book reviews. Alex Field oversees the Book Review department and Moses Abramovitz assists me with the articles. Our work is supported by Anita Makler, Britt Ellis, and Toni Haskell. Ann Vollmer retired during the year and I wish to express my gratitude to her for her devoted service to the Association.

The expository and review articles appearing in the *Journal* are commissioned by the editor. However, I welcome proposals for such articles especially if such proposals are accompanied with a clear statement of the article's goals and an outline of its intended contents. All of our published articles go through a careful refereeing process.

I am most grateful to our referees for their very real assistance. I list at the end of this report the names of those referees who helped us during 1990 with manuscripts and proposed manuscripts. Many of these people wrote magnificent reports and made significant contributions to the quality of our articles.

The *Journal* has also benefited from the advice of its Board of Editors. Mark Rosenzweig's term on the Board will be completed by the end of 1990. I am very grateful to him for his careful work on behalf of the *Journal*. The terms of Richard Marston, Thomas Mayer, Robert Pollak, and Harvey Rosen are also coming to an end, but fortunately they have agreed to serve another term. Their service has been outstanding. I shall be proposing to the AEA Executive Committee that Sherman Robinson join the Board next year.

JOHN PENCANEL, *Editor*

Report of the Editor

Journal of Economic Perspectives

The end of 1990 marks three-and-one-half years of publication of the *Journal of Economic Perspectives*. During that time, the *Journal* has been evolving from complete newcomer to familiar face. As far as the editors can judge, the first 14 issues of the *Journal* have developed a reputation for interest and clarity, and a loyal ongoing readership.

The *Journal* has continued the pattern set in years past of addressing a broad range of topics in several different formats. The issues of 1990 included 6 symposia: new institutions for developing country debt; welfare and workfare; bubbles; the state and economic development; collaboration, innovation, and antitrust; and the economic status of African-Americans. They also included 4 articles about well-known economists (Houthakker, Kreps, Pechman, and Goldberger), and 12 articles on various other topics, ranging from bimetallism to socialist economics, from micro-macro simulation to the econometrics of kinked budget constraints, from optimal taxation to state lotteries, and others. In addition, the *Journal* also continued publication of several regular features—"Puzzles," "Anomalies," "Recommendations for Further Reading," along with Notes and Correspondence.

Two new features began in 1990, as well. "Retrospectives" will be aimed at topics in the history of economic thought, while "Policy Watch" will deal with policy topics of immediate relevance. In 1991, these new features will partly replace the "Puzzles" and "Anomalies" columns.

In total, the 1990 issues of the *Journal* included 896 pages, consisting of 36 articles, 5 introductions or very brief articles, 16 of the features articles, plus Notes and Correspondence. In the two previous years, the *Journal* had published a total of 832 pages, so the number of journal pages increased by about 8 percent in 1990. This was mainly due to an increase in the short feature arti-

cles from 11 in 1989 to 16 in 1990. As we publish fewer columns of puzzles and anomalies in 1991, the 1991 page total should decline from the 1990 level.

The decentralized editorial procedure of the *Journal* has continued to work well, as the list of articles illustrates. The Associate Editors have continued to generate lists of ideas and potential authors, enabling the *Journal* to draw on a large group of economists with diverse interests and perspectives. A process of natural turnover seems to have developed among the Associate Editors, allowing several new members to bring their ideas to the *Journal* each year.

Many readers have let us know that they would like to see some articles about the recent changes in the Soviet Union and Eastern Europe. One of the new Associate Editors for 1990 (Peter Murrell of the University of Maryland) will take on the responsibility of soliciting articles about these topics. The *Journal* plans to publish a lengthy symposium on these events in its Fall 1991 issue, and then several follow-up articles in future years.

As in years past, the *Journal* has had no difficulty in finding authors who were willing and eager to write. The broad readership of the *Journal* seems especially attractive to potential authors and also makes them willing to work hard on revising and reshaping their articles in order to make them accessible to that broad audience. As a result, the issues of 1991 are almost fully booked with articles of high quality, and advance planning for 1992 and 1993 is well underway.

The incumbent Associate Editors who will continue into 1991 are: Henry Aaron, The Brookings Institution; Pranab Bardhan, University of California-Berkeley; James Heckman, Yale University; Dwight Jaffee, Princeton University; N. Gregory Mankiw, Harvard University; Barry Nalebuff, Yale University; John Roemer, University of Cal-

ifornia-Davis; Sherwin Rosen, University of Chicago; Bernard Saffran, Swarthmore College; Steven Salop, Georgetown University; Hal Varian, University of Michigan; Gavin Wright, Stanford University; Janet Yellen, University of California-Berkeley.

Members of the *Journal's* Advisory Board have continued to provide helpful advice, including feedback on past articles and suggestions for future ones. The *Journal* has continued its tradition of holding a breakfast each year at the annual meetings, so that members of the Advisory Board, the Associate Editors, and the Editors can meet to brainstorm and exchange views about the *Journal*.

The staff of the *Journal* remained the same in 1990. Debbie Sachs held the position of Editorial Associate. The day-to-day job of running a journal requires a considerable array of personal, management, and administrative skills. Debbie's flexibility, good humor, and attention to detail have

been essential to the smooth functioning of the *Journal*.

As in years past, the Editors feel that they cannot overstate the role that Managing Editor Timothy Taylor has played in the operation of the journal. He has managed the day-to-day operations of the *Journal* smoothly and ensured that the fundamental objectives of the *Journal* are satisfied. He has performed the difficult task of persuading authors to amend and rewrite their articles with delicacy and skill, and has shown that it is possible to edit papers and increase their clarity and accessibility, while still retaining the distinctive voice of each author.

Requested action: 1) Approval of new members to join the Editorial Board in 1991: Peter Murrell, University of Maryland; Gene Grossman, Princeton University.

JOSEPH STIGLITZ, *Editor*
CARL SHAPIRO, *Co-editor*

Report of the Director

Job Openings for Economists

The total number of new jobs listed decreased from 2,014 last year to 1,875 this year. Academic jobs increased from 1,411 to 1,447, but nonacademic listings declined to 428 from 603. Table 1 shows total listings (employers), total jobs, new listings, and new jobs by type for each issue of *JOE* in 1990.

Table 2 shows the number of employers by category (four-year colleges, universities with graduate programs, federal government, etc.) for each of the seven issues. Academic institutions continue to be the major advertisers, about 77 percent of the total number of employers listing vacancies.

Administrative Positions (B00)	11	4	6	5	13	9	11	59
Totals	272	180	124	201	784	537	785	2,883

Note: Fields of specialization codes are from the *Journal of Economic Literature*.

The distribution of employers by type has been roughly the same for the past several years.

Table 3 shows the number of listings by field of specialization. Once again, General Economic Theory (which includes both micro and macro) led in popularity, and Monetary and Fiscal (300) was second. International Economics (400) beat out Econometrics and Statistics (300) for third—a change in the usual pattern that has prevailed over many years. The new classi-

fication scheme of the *JEL* will be utilized next year. The new categories, especially the breaking up of General Economic Theory into more detailed specialties, will reveal more about which fields are “hot.”

Violet Sikas continues to be the “one-woman band” for *JOE*. Without her, the Director might have to do some work. I am grateful for all that she does.

C. ELTON HINSHAW, *Director*

Report of the Committee on Economic Education

The third edition of the *Test of Understanding College Economics* (TUCE III) is now available from the Joint Council on Economic Education, 432 Park Avenue South, New York, New York 10016. The TUCE III consists of a 33-item, four-option multiple-choice test in macroeconomics and a 33-item, four-option multiple-choice test in microeconomics. The last three questions on each test deal with international economics concepts. This enables instructors who do not cover international economics in the macro course (or in the micro course) to use the first 30 questions as a "pure" macro (or micro) test.

The overall content and cognitive specifications for TUCE III are similar to those of previous editions, but only three of the questions on the macro test and only four of the questions on the micro test have exactly the same wording in TUCE III as in TUCE II. A set of macro norming data collected from 92 sections at 46 institutions and a set of micro norming data collected from 96 sections at 49 institutions is reported and interpreted by Phillip Saunders of Indiana University in the *Interpretive Manual* that accompanies TUCE III. Saunders is in the process of compiling an extensive set of student and instructor information provided by the norming institutions. When completed, this data set should be of considerable interest to researchers who want to analyze and interpret student performance on TUCE III in a variety of different institutions. Like TUCE itself, the *Interpretive Manual* and the forthcoming data set will be available from the Joint Council on Economic Education.

The Association of American Colleges (AAC) has completed its project on study-in-depth. The AEA Committee on Economic Education participated in the project along with eleven other arts and science disciplines. A task force of six economists (all but one of whom are current members or former chairs of the Committee) has completed an extensive report on the eco-

nomics major. The report documents the number of students who have majored in economics over the last two decades, attempts to describe a consensus view of the purpose of the major, describes the typical curriculum, examines several pedagogical issues (class size, instructional methods, writing, perspective on the methodology of economics, and the effect of teaching methods on students of different ages, race, and gender), concludes that we know little about what our students learn in the major, and makes a series of recommendations to improve the experience of students who major in economics. The complete report is scheduled to appear in the Summer 1991 issue of the *Journal of Economic Education* along with comments by two discussants. A shorter version appears along with essays on the major in eleven other disciplines in a volume published by the AAC. A summary of the paper along with the recommendations is part of the proceedings of the December 1990 AEA meetings.

There has been considerable research on high school economics in recent years. A grant from the Pew Trust to the Joint Council on Economic Education in the late 1980's nurtured this growth. The Economics Education Session sponsored by the Committee on Economic Education at the December 1989 AEA meetings focused on the new research results which emanated from the Pew Project. To build on this momentum, the Committee recommended preparation of a survey of the research literature on high school economics similar to the survey of research on teaching college economics that was published in the *Journal of Economic Literature* in 1979. Work on the survey article is underway.

The Committee devoted a special meeting in 1989 to establishing an agenda for its work in the 1990's. A subcommittee produced an agenda statement, which is part of the *Proceedings* of the December 1990 AEA meetings. The Committee plans to focus on three areas: 1) Expanding and improving

our ability to assess learning (particularly above the principles level, and especially with instruments other than multiple-choice tests); 2) Learning more about the economics major; and 3) Developing data sets and encouraging researchers to reexamine

many of the important empirical issues in economics education with improved data sets and modern empirical methods.

JOHN J. SIEGFRIED, *Chair*

Report of the Committee on the Status of Minority Groups in the Economics Profession

The primary mission of the Committee on the Status of Minority Groups in the Economics Profession (CSMGEP) is to increase the representation of minority groups in economics. The targeted groups are those that are underrepresented within the field, particularly African-Americans, Hispanics, and Native Americans. The Committee has had three organized programs to facilitate the achievement of this objective—the AEA Summer Minority Program, the AEA/Rockefeller graduate fellowship program, and the AEA/FRS dissertation fellowship program. Together they have provided supplementary preparation for graduate study and the financial support that would allow students to complete their Ph.D.s in economics. During 1990, only the summer program and the dissertation fellowships were in operation and significant changes were made in both of them.

AEA Summer Minority Program. The summer program is designed to increase the probability that promising minority undergraduate students enter and complete Ph.D. programs in economics. It has been in operation since 1974, providing minority undergraduate students (rising seniors) with an eight-week program of theoretical and applied economics. This year marked the fifth and final year for Temple University to serve as host for the junior summer program.

In 1989, the CSMGEP solicited applications from universities to replace Temple as the host institution and, by the beginning of 1990, four completed applications were received. All four institutions indicated a willingness to commit substantial resources, over and above the support to be provided by the AEA. Stanford University was selected as the new host for the summer program, and they have made information on the program available through advertisements and direct mailings. The principal features of the Stanford program include a highly analytical curriculum, course credit and transcripts for students completing the

courses, and weekly policy seminars. The program will be directed by Thomas MaCurdy of the Economics Department, but includes participation by both the Food Research Institute and the Graduate School of Business at Stanford.

AEA / FRS Fellowship. The Federal Reserve System has sponsored a program in conjunction with the AEA which provides financial support to the third, fourth, and possibly fifth-year minority graduate students who are writing dissertations in areas of interest to the Federal Reserve. This support has been renewed for a five-year period, beginning with the 1991–92 academic year. The stipend has been raised to \$900 per month for the academic year, and it includes a requirement that students spend the summer after their first fellowship year as an intern at the Board or at one of the Federal Reserve Banks. Up to ten awards will be made each year.

During the 1990–91 academic year, support is being provided to Grover McArthur at The New School for Social Research, Victor Mendes at Syracuse University, and Gregory Price at the University of Wisconsin-Milwaukee. Among the group of recipients during the 1989–90 academic year, Philips Jefferson completed his Ph.D. at the University of Virginia.

Other Activities. The Committee has the obligation of seeking funding to replace the AEA/Rockefeller fellowship program, which provided support for the first and second years of graduate study. Sources of funding were identified in 1990 and proposals will be developed and submitted in 1991. The development of a program that would increase interest in economics among college sophomores is being considered, possibly in conjunction with other organizations, such as the National Economic Association.

A survey of past participants in the summer program was conducted in 1990 and results are being tabulated. In the future, more frequent surveys of program partici-

pants will be carried out, in conjunction with the program's host institution.

On July 1, Ronald Oaxaca completed his term as Chair of CSMGEP. William A.

Darity, Jr. ended his second term on the Committee at the end of the year.

MARGARET C. SIMMS, *Chair*

Report of the Committee on the Status of Women in the Economics Profession

The Committee on the Status of Women in the Economics Profession (CSWEP) has been charged by the American Economic Association with monitoring the position of women in the profession and undertaking activities to improve it. This Report examines the advancement of women economists in academia, compares this progress with what might be expected, and describes the Committee's activities during the past year.

Are Women Economists as Likely as Men to be Hired and Promoted?

The proportion of assistant professors who are women has been rising as one would expect based on the growing proportion of Ph.D.s in economics awarded to women, but their progress into the ranks of associate and full professor appears to be lagging somewhat. This conclusion is based primarily on data about graduate economics departments (defined as those that award Ph.D.s) that responded to the AEA's Universal Academic Questionnaire (UAQ) between 1974 and 1989.¹

Two parallel analyses of full-time faculty were conducted for this Report: One used data from 150 graduate economics departments that responded to the questionnaire in any year, while the other examined the 43 departments that responded in almost every year.² Because of the similarity in results, only the analysis for the larger sample of departments is reported here.

The proportion of assistant professors and of associate professors who were women approximately tripled between 1974 and 1989—rising from 8 to 20 percent and from

FIGURE 1. PROPORTION OF FACULTY IN
GRADUATE DEPARTMENTS WHO ARE WOMEN
By Rank, 1974-89

3 to 9 percent, respectively (see Figure 1).³ In contrast, the proportion of full professors who were women grew from about 2 percent in the late 1970's to about 3 percent in the late 1980's. Because about one-half of all tenure-track and tenured economics faculty at departments in the sample were full professors, the proportion of all faculty who were women was about 9 percent in 1989. This represented a doubling of the proportion from 1970's.

Differences in the employment of women faculty by different types of institutions have not been dramatic. Women assistant professors of economics were somewhat more likely to be employed by public institutions in the 1980's than men, while there was little difference between public and private institutions for associate or full professors (see Figure 2). When departments are ranked by the scholarly quality of their faculty, it appears that women assistant professors might have been employed by lower-quality schools relatively more often than men during the 1980's; whereas, there was

¹The Committee thanks Eric Guille, Jodi Korb, Charles Scott, Arantza Ugidos, Jackie Vander Brug, and Bruce Vavrichek for their contributions to this Report.

²In both cases, departments of agricultural economics were excluded. The 43 departments are those that did not respond in at most two consecutive years.

³In this analysis, the proportion who are women is always of the comparable group of faculty—in this case, it is the percent of faculty with the same rank who are women. (The source for all figures herein is the UAQ.)

FIGURE 2. PROPORTION OF FACULTY IN GRADUATE DEPARTMENTS WHO ARE WOMEN BY RANK AND TYPE OF INSTITUTION, 1974-89

FIGURE 3. PROPORTION OF FACULTY IN GRADUATE DEPARTMENTS WHO ARE WOMEN BY RANK AND QUALITY OF DEPARTMENT, 1974-89

little difference for associate or full professors, as shown in Figure 3.⁴

How does the progress of women through the academic ranks compare with what would be expected if hiring and promotion decisions were unaffected by gender? Figure 4 shows that the proportion of newly hired assistant professors who were women has risen as expected—it resembled the proportion of new recipients of Ph.D.s in economics who were women, at least until late in the 1980's.⁵

⁴The scholarly quality of economics departments was based on data for 93 graduate economics departments reported in National Research Council, *An Assessment of Research-Doctorate Programs in the United States: Social and Behavioral Sciences* (Washington: National Academy Press, 1982). The data examined here included 88 of those departments; the remaining 62 departments (of the 150 on which this report is based) that were not included in the NRC's study were excluded from the calculations for Figure 3.

⁵Data on newly awarded Ph.D.s in economics are reported in National Science Foundation, *Science and*

FIGURE 4. PROPORTION OF NEWLY HIRED ASSISTANT PROFESSORS IN GRADUATE DEPARTMENTS, AND PROPORTION OF NEWLY AWARDED PH.D.S IN ECONOMICS WHO ARE WOMEN, 1974-89

FIGURE 5. PROPORTION OF NEW ASSOCIATE AND FULL PROFESSORS IN GRADUATE DEPARTMENTS WHO ARE WOMEN, 1974-89

The proportion of newly hired or newly promoted associate (and full) professors who were women has also been rising, as shown in Figure 5, but assessing this growth is more difficult because, a priori, it is not clear what the standard of comparison should be. To deal with this problem, actual data were compared with the results of a simple model that simulates the promotion process in academia. The assumptions underlying the model were determined by data about the flow of faculty into each rank (i.e., newly hired individuals and those promoted from the lower rank), and about the flow

Engineering Doctorates: 1960-1989. They are based on all graduate departments on the United States. In Figure 4, data on newly awarded Ph.D.s are for U.S. citizens and noncitizens who are permanent residents. Temporary residents are excluded.

out of each rank (i.e., faculty who left the department and those who were promoted into the next rank).⁶ In particular, the model assumes that, on average, full professors remain in a department for 20 years; that promotion to full professor is decided, on average, 7 years after promotion to associate professor; that promotion to associate professor is decided, on average, 5 years after being hired as an assistant professor; and that women are hired as assistant professors in the same proportion as they receive newly awarded Ph.D.s in economics.⁷ In addition, the model assumes that the distribution of talent and motivation is the same for female economists as for male economists and, hence, that the probability of an individual being promoted is not related to gender.

Figure 6 compares the implications of the model with what actually happened. The proportion of assistant professors who were women increased as the model projects over the 1974–89 period, with the actual proportion exceeding the projected one in the first half of the period and falling below for much of the second half. In contrast, the actual proportions of associate professors and full professors who were women have been below the levels projected by the model in most years and consistently below since 1982.

FIGURE 6. ACTUAL AND SIMULATED PROPORTION OF FACULTY IN GRADUATE DEPARTMENTS WHO ARE WOMEN, BY RANK, 1974–89

These results can be seen as both discouraging and encouraging. Unfortunately, they support the belief that women's progress to the ranks of associate and full professor has been slower than it should have been. More positively, though, they indicate that any shortfall (especially in the proportion of full professors who are women) is considerably less than might be assumed based on the much faster growth in the proportion of assistant professors who are women. In other words, that simple comparison neglects the fact that, on average, it takes more than a decade to advance from assistant to full professor.

What might we conclude about the future? On the one hand, the rising proportion of assistant professors of economics who are women indicates that there is a growing pool of women to be promoted to associate and full professor. On the other hand, if women assistant professors are disproportionately located at lower-quality departments, growth in the proportion of associate and full professors who are women may be limited at the better schools. Moreover, the actual increase in the proportion of full professors who are women over the next decade will be largely constrained by what has already happened for associate professors. Yet, the actual proportion of associate professors who are women has been noticeably below the simulated proportion since 1982. Thus, the gap between the actual and the simulated proportion of full professors who are women is likely to grow in coming years. While future research

⁶For each year, the percentage of faculty in each of these categories was averaged over the departments that responded in that year. Because these percentages were reasonably stable over the 1974–89 period, the 16-year averages were used in the simulation model.

⁷In 1975, for example, the model assumes that the proportion of faculty leaving the rank of full professor who were women depended on the proportion of doctoral recipients who were women in 1943 (i.e., 32 years earlier because these faculty, on average, spent 20 years as full professors and took 12 years to reach that rank after being hired as assistant professors). Because actual data on doctoral reciprocity were not available for years prior to 1960, the model assumes that the proportion awarded to women was 4 percent in each earlier year—about the same as in the early 1960's. This assumption is conservative (i.e., it tends to lower the projected proportion of full professors who are women) because doctoral reciprocity in the early years affects only the simulated outflow of women full professors.

may be able to shed some light on why these patterns persist, expanding women's participation in the economics profession may also require examining the interpersonal dynamics within graduate programs and departments.

The Committee's Recent Activities

CSWEP pursued several activities in 1990 designed to help women advance in the economics profession. As part of its ongoing efforts to expand the participation of women economists on the program of the AEA's annual meetings, the Board organized six sessions for 1990—three on gender-related topics and three on technology and productivity. In addition, each person asked by the President-elect to organize an invited-paper session was sent a list of experienced women economists who specialize in the same fields as the organizer. These reminders of possible participants have been associated with greater participation of women.⁸ As well, to facilitate networking at the annual meeting among economists who support CSWEP's goals, CSWEP sponsored a hospitality suite and a reception followed its business meeting.

Another major activity was publishing three issues of the CSWEP *Newsletter*, the contents of which are designed primarily to help young economists advance. Each issue contains information about sources of research funding and calls for papers, as well as articles on topics such as the annual job market and tips on writing publishable articles. In response to many requests for copies of articles from earlier issues, the Board also reprinted selected articles in a fourth

issue of the *Newsletter* that is available free to dues-paying members, or for \$8.

Updating and expanding the entries in the *Roster of Women Economists* absorbed a considerable amount of the Board's resources. The *Roster* contains information about women economists, including their employers, educational backgrounds, fields of specialization, and publications. It is used by employers searching for job candidates and by organizations seeking members of advisory committees and the like. The entire *Roster*, or selected portions of it, are available in computer-readable form or as mailing labels. In addition, the *Roster* appears in a printed volume every other year. The Board also continued its recent practice of informing advertisers in *Job Openings for Economists* and the CSWEP *Newsletter* about the *Roster* and how to use it.

Finally, the Board thanks Joan Haworth, the Committee's Membership Secretary, and her staff for their many contributions—maintaining the *Roster*, updating it using the AEA's membership directory, preparing special mailings, and creating customized listings from the *Roster*, to name just a few. The Board is also grateful to three members whose terms expire this year. Shulamit Kahn organized many sessions and coordinated information about the availability of child care for several annual meetings of the AEA. She has also agreed to continue participating in an ongoing CSWEP-sponsored research project comparing the career paths of female and male economists. Kathryn Morrison and Barbara Newell each co-edited an issue of the *Newsletter* and helped with projects to expand use of the *Roster*. The Board also thanks Jill Bury, who continues to contribute a great deal, including doing an outstanding job producing the *Newsletter*.

NANCY M. GORDON, *Chair*

Report of the Committee on U.S.-China Exchanges in Economics

Modern economic education and research continued to develop in China in 1990 as evidenced by the following events.

1) American economists continued to teach in China, including the two graduate economics training centers at the People's University in Beijing (Harold Watts of Columbia University and Kajal Lahiri of the State University of New York at Albany in Spring 1990; Mark Machina of the University of California-San Diego and Belton Fleisher of Ohio State University in Fall 1990) and at Fudan University in Shanghai (Alastair MacBean of Lancaster University and Sumner LaCroix of the University of Hawaii in Spring 1990; Dudley Wallace of Duke University and Albert Schweinberger of Australian National University in Fall 1990), and Lingnan (University) College at Zhongshan University in Guangzhou (Anthony Koo of Michigan State University).

2) A delegation of deans and chairmen of colleges and departments of economics headed by the Dean of Economics at the People's University, Yu Xueben, visited the United States on October 27 to November 18 to study economic education in the United States. The seven major universities represented were Fudan, Jilin, Nankai, Peking, the People's, Wuhan, and Xiamen universities. Besides visiting Columbia, Harvard, Washington, D.C., and Stanford, the delegation spent ten days at the University of Michigan, hosted by Michael Oxenburgh of the Center for Oriental Studies and Robert Dernberger of the Department of Economics, and participated in intensive discussions on the administrative and academic aspects of American economic education. Other visitors from China included visiting fellows supported by The Ford Foundation. Dr. Justin Lin of the Rural Development Department, Development Research Center of the Chinese State

Council and Beijing University, served as Visiting Associate Professor at the University of California-Los Angeles, in the fall quarter 1990.

3) An International Conference on Quantitative Economics and Its Applications to Chinese Economic Development and Reform in the 1990's, sponsored by the Chinese Academy of Social Sciences and the United Nations Development Programme in China, took place in Beijing, June 24-28. Sixteen foreign economists participated, mostly American, but including French, Hungarian, and Taiwanese economists. The conference was to celebrate the tenth anniversary of the Econometrics Workshop organized by Lawrence R. Klein of the University of Pennsylvania and Xu Dixin of the Chinese Academy of Social Sciences in Beijing in the summer of 1980. The instructors of the 1980 workshop, including Albert Ando, Gregory Chow, Cheng Hsiao, Lawrence Klein, Lawrence Lau, and Vincent Su returned to Beijing to present papers and to visit the site of the 1980 workshop. A number of papers were presented by Chinese scholars, including those of the Chinese Academy of Social Sciences doing cooperative research with their American colleagues.

4) The Chinese State Education Commission continued to develop modern economic education by introducing the core courses of micro, macro, statistics, accounting, international trade, economic development, and money and banking, which were adopted in 1988. In the summer, a number of workshops were organized to train the university teachers to teach some of these core courses. Winston Chang of the State University of New York at Buffalo and Frank Hsiao of the University of Colorado were among the visiting professors teaching the workshops.

GREGORY C. CHOW, *Chair*

Report of the Representative to the National Bureau of Economic Research

The National Bureau of Economic Research studies a wide variety of economic issues. Much of this research is conducted by economists working individually, but a large part is organized into special projects. To disseminate the results of this research, during 1990 the NBER issued almost 400 working papers, published 10 books, 2 NBER journals, prepared 6 special issues of other journals, and circulated the monthly *Digest* and the quarterly *Reporter*. In addition, the NBER held numerous conferences and workshops, including the 6-week long Summer Institute. Finally, the NBER hosted three Olin Fellows and two Aging Fellows who spent the year conducting empirical research on a variety of empirical topics.

Programs. The NBER's ongoing programs generally meet twice during the academic year, and once, for a longer period, during the Summer Institute. Bureau programs (directors in parentheses) are Economic Fluctuations (Robert Hall), Financial Markets and Monetary Economics (Benjamin Friedman), International Studies (William Branson), Labor Studies (Richard Freeman), Taxation (David Bradford), Development of the American Economy (Robert Fogel and Claudia Goldin), Health Economics (Victor Fuchs and Michael Grossman), and Productivity (Zvi Griliches). In 1990, Nancy Rose became the director of a new Bureau program in Industrial Organization.

Projects. The NBER's projects generally bring a dozen or more researchers together to work on a common topic. The projects' findings are usually distributed initially as NBER working papers, and final versions are then published as Bureau books. During 1990, the following projects (organizers in parentheses) were underway: Trade and Immigration (George Borjas and Richard Freeman), Economic Growth (Robert Barro and Paul Romer), Economics of Higher Education (Charles Clotfelter and Michael Rothschild), Financial Crisis

(Glenn Hubbard), Tax Reforms in Asia and the U.S. (Anne Krueger and Takatoshi Ito), Macroeconomic History (N. Gregory Mankiw and Christina Romer), Politics and Economics in the 1980's (Alberto Alesina and Geoffrey Carliner), Exchange Rate Targets and Currency Bands (Paul Krugman and Marcus Miller), Trade Policy and the Uruguay Round (Robert Baldwin and David Richardson), Taxation in the U.S. and Canada (John Shoven and John Whalley), Macro Policies and Income Distribution in Latin America (Rudiger Dornbusch and Sebastian Edwards), Economics of Aging (David Wise), and American Economic Policy (Martin Feldstein).

Other Conferences. In addition to the conferences and workshops conducted as part of NBER projects and programs, the NBER also holds larger conferences open to individuals in government and academe. During 1990, these included a session of the Conference on Income and Wealth on the Measuring Service Sector Output, organized by Zvi Griliches; a Universities Research Conference on Asset Pricing and Financial Markets, organized by John Campbell; and a second URC on Exchange Rate Regimes, organized by Alberto Giovannini. Procedures and deadlines for submitting papers to these conferences are posted in economics departments and announced in the *NBER Reporter*.

Summer Institute. During the summer of 1990, 642 economists from 180 different universities and research organizations attended the Summer Institute, including 255 participants who came for the first time. Participants stayed for periods ranging from 4 days to 2 months. There were 273 papers presented in 36 separate sessions. A catalogue of these papers, including authors and their addresses, is available from the NBER on request.

Working Papers. NBER working papers are circulated to economics department libraries around the world, and are available

from the NBER for \$3 per title in the United States and \$4 elsewhere. Subscriptions to the entire series are available for \$500 per year inside the United States and slightly more elsewhere.

Books. The 10 books published by the NBER during 1990 included monographs by Robert Gordon on measuring durable goods' prices and by Robert Margo on race and schooling in the South, 1880–1950. Assaf Razin and Joel Slemrod edited a volume on international taxation. William Branson, Jacob Frenkel, and Morris Goldstein edited a volume on international policy coordination and exchange rate fluctuations.

Journals. The NBER publishes two journals, which appear once each year. Olivier Blanchard and Stanley Fischer edited the *Macroeconomic Annual* in 1990, and Lawrence Summers edited *Tax Policy and the Economy*. Subscriptions for these two journals can be ordered from MIT Press.

In addition, the NBER sponsored special issues of several journals. Tony Atkinson and David Bradford edited papers on the future of the welfare state for the *Journal of Public Economics*. Sanford Grossman organized the *Review of Financial Studies* symposium on stock market volatility. Robert Gordon and Georges de Menil edited papers on international macroeconomics for

the June issue of the *European Economic Review*. Edmar Bacha and Sebastian Edwards edited papers on Latin America for publication in the *Journal of Development Economics*. John Campbell and Angelo Melino organized the issue of the *Journal of Econometrics* on financial times-series.

Periodicals. The monthly NBER *Digest* provides brief summaries of working papers of general interest. The quarterly *Reporter* contains longer summaries of recent research, abstracts of all working papers, announcements of the publication of NBER books, and a calendar of forthcoming conferences. Both these periodicals are available on request.

Olin Fellows. The three Olin Fellows for the 1990–91 academic year are Lawrence Ball, Robert Gibbons, and Dani Rodrik. These fellowships are open to young empirical economists at any academic institution. The two Aging Fellows are Ed Norton and Leslie Papke.

During 1990, Martin Feldstein continued as President of the NBER and Geoffrey Carliner continued as Executive Director. Further information on NBER activities is available in the *Reporter*, or from Geoffrey Carliner, NBER, 1050 Massachusetts Avenue, Cambridge, MA 02138.

DAVID KENDRICK, *Representative*

Report of the Representative to the American Association for the Advancement of Science

The American Association for the Advancement of Science is a federation of scientific organizations, as well as an association of over 130,000 individual members. Its objectives are "to further the work of scientists, to facilitate cooperation among them, to foster scientific freedom and responsibility, to improve the effectiveness of science in the promotion of human welfare, and to increase public understanding and appreciation of the importance and promise of the methods of science in human progress."

The discipline of Economics is grouped with Political Science, Sociology, Geography, and some related social sciences in Section K, one of the twenty-one divisions within the AAAS. Most economists list Section K as their primary affiliation, and some hold dual or multiple membership in other sections. Overall, the four social science sections comprise just under 10 percent of the AAAS-affiliated membership.

The AAAS offers economists a unique opportunity to interact with the scientific community at large. This includes the following channels: the AAAS annual meeting, joint sessions with other organizations at their professional meetings, speciality conferences, *Science*, and AAAS-sponsored books. In addition, the organization is active through the work of its offices and standing committees on Science and Technology Education, Public Sector Programs, Opportunities in Science, International Science, Scientific Freedom and Responsibility, and Science, Arms Control, and National Security.

A joint AEA/AAAS session was held at the 1990 Allied Social Science meetings on "R&D Spillovers and Externalities." The session was chaired by Richard Levin and included papers by Jess Benhabib and Boyan Jovanovic, Jeffrey Bernstein and M. Ishaq Nadiri, Edwin Mansfield, and Adam Jaffee and Rebecca Henderson.

Three of the symposia and five of the technical sessions at the 1990 AAAS meet-

ing in New Orleans received the endorsement of the AEA/AAAS Liaison Committee. In addition, AEA members organized or contributed to other sessions. Economists participating in the annual AAAS meeting included John Antle, Gilbert Bassett, Robert Evenson, Donald Hanson, Richard Kosobud, Lester Lave, William Nordhaus, Mancur Olson, James Opaluch, Paul Portney, Clifford Russell, Roger Sedjo, James Smith, Andrew Solow, and Gary Yohe. Session topics covered a diversity of topics such as Foreign Assistance and Environmental Problems in LDCs, Economic Perspectives on Biotechnological Development, Managing Outer Continental Oil and Gas Resources, and Agricultural Chemicals and Water Quality.

Through the efforts of the AEA/AAAS Liaison Committee and the AEA membership, economists have been more active than other social scientists at the AAAS annual meeting. Our continued success at getting sessions devoted to economics on the program is dependent on the submission of high quality proposals and strong attendance. AEA members are encouraged to take part at future AAAS meetings, the next one to be held in Chicago in February 1992.

Continuing the trend of the past 2 years, several economists were commissioned to write papers for *Science*. Authors of commissioned or contributed papers included: Victor Fuchs, John Kennan, Robert Litan, Ronald Mincy, Alvin Roth, Isabell Sawhill, Peter Suchman, W. Kip Viscusi, Robert Wilson, Douglas Wolf, and Richard Zeckhauser. Robert Solow and Elizabeth Bailey continue to serve on the Editorial Board of *Science* and Robert Dorfman on the publication's Board of Reviewing Editors.

Several AEA members are officers of Section K. They include: Mancur Olson (Retiring Chair), Marc Nerlove (Chair-Elect), Robert Fogel and Amitai Etzioni (Section Committee Members), Richard Cyert, Lester Lave, and T. Paul Schultz

(Electorate Nominating Committee Members), and William Alonso (Council Delegate).

More than 30 economists are fellows of the AAAS. This past year the names of Albert Rees, Vernon Smith, and Sidney Winter were added to these ranks.

Further information about the AAAS is available from Marge White, 1333 H Street,

N.W., Washington, D.C. 20005. AEA members are also encouraged to contact members of the AEA/AAAS Liaison Committee: Roger Bolton, Gardner Brown, Faye Duchin, Adam Rose, Vernon Smith, and Robert Solow, about AAAS activities.

ADAM ROSE, *Representative*

Policy and Advisory Board of the Economics Institute

The Institute's first year under its new Director, Charles Becker, who succeeded Wyn Owen January 1, 1990, has been a good year. For several years prior to 1990, Economics Institute enrollments had declined because of developing country debt problems and a shortage of scholarship funds. These trends were reversed in 1990.

Total student enrollments increased almost one-third from 1989 to 1990, and student term equivalents increased 46 percent. Total revenues increased commensurately. Revenue increases enable the Institute to offer financial aid to more students whose funds cannot cover the full cost of the program. Enrollment increases were broadly based, with increasing numbers of students attending from many countries. Pervasive economic growth has enabled many countries to sponsor more students at the Institute and in U.S. graduate programs. In addition, U.S., source-country institutions, and international organizations have been able to sponsor more students.

Because of increased enrollments and revenues, the Institute has been able to broaden its preparatory work for graduate programs in economics, agricultural economics, and business. The Institute now offers a wide range of coursework in English, economic theory, mathematical economics, statistics, econometrics, and computer analysis. It is the only preparatory program that carefully integrates teaching of English with subject matter instruction. Especially impor-

tant has been expansion and upgrading of courses and laboratories in computing. Many students arrive at the Institute with little or no experience with modern computers. Computer facility is crucial not only for subsequent graduate study in the United States, but also for effective research and analysis after returning to home countries. Also important in upgrading the Institute's instructional program has been the acquisition of a state-of-the art Song language laboratory.

Among the large challenges that face the Institute in 1991 and subsequent years will be to satisfy the needs of substantial numbers of students from Eastern Europe and China.

Present Board members are: Daniel Bromley (University of Wisconsin-Madison), John Evans (University of North Carolina-Chapel Hill), Koichi Hamada (Yale University), Lawrence Lau (Stanford University), Ray Marshall (University of Texas-Austin), James Millar (University of Arkansas), Samuel Morley (Vanderbilt University), and Edwin Mills (Northwestern University).

Programs and institutions interested in further information about the Institute should contact Director, Economics Institute, 1030 13th Street, Boulder, CO 80302 (telephone 303-492-3000; Telex 450385 ECONINSTBDR).

VICTOR R. FUCHS

DISTINGUISHED FELLOW

1990

Victor R. Fuchs is widely recognized as one of the founders of health economics, and his research has touched on every aspect of this field. He also has done important research in industrial organization and labor economics. These latter contributions are highlighted in his fascinating work on the service economy. Here one finds a variety of carefully crafted empirical studies on trends in productivity and employment in the service, industry, and agricultural sectors; inter-industry and intersectoral differences in hourly earnings; and cyclical fluctuations in productivity.

His research in health consists of studies ranging from the economic determinants of mortality rates and the roles of schooling, time preference, and cigarette smoking in health outcomes, to detailed analyses of the markets for physicians' and surgeons' services and to the implications of health policy reforms in the United States. This research reflects themes for which Fuchs has become justly famous, including the importance of individual behavior in health outcomes and the key role played by physicians in the market for their services.

Fuchs has stressed that research should be empirically sound and policy relevant. He also is to be commended for his prodigious efforts to make the key insights of economics available to physicians and policymakers. The American Economics Association honors a truly outstanding empirical researcher who uses economic theory to better understand and improve the environment in which we live.

Editorial Statement

It is the policy of the *American Economic Review* to publish papers only where the data used in the analysis are clearly and precisely documented, are readily available to any researcher for purposes of replication, and where details of the computations sufficient to permit replication are provided. The Editor should be notified at the time of submission if the data used in a paper are proprietary, or if, for some other reason, the above requirements cannot be met.

Popular Attitudes Toward Free Markets: The Soviet Union and the United States Compared

By ROBERT J. SHILLER, MAXIM BOYCKO, AND VLADIMIR KOROBOV*

Random samples of the Moscow and New York populations were compared in their attitudes toward free markets by administering identical telephone interviews in the two countries in May 1990. Although the Soviet respondents were somewhat less likely to accept exchange of money as a solution to personal problems and although their attitudes toward business were less warm, we found that the Soviet and American respondents were basically similar in some very important dimensions: in their attitudes toward fairness, income inequality, and incentives and in their understanding of the working of markets. (JEL O57)

What are the important barriers to the success of free markets? At this time of transition in the Soviet Union and other Eastern economies, the answer to this question is of the utmost importance. One view is that major obstacles are the attitudes, morals, and understandings of the people themselves, not just the institutions or politics they live with. Leonid Abalkin, former Deputy Prime Minister of the Soviet Union and prominent economist, complained that

...it is not easy to develop a stratum of talented people, with a good under-

standing of the market. For that, it is necessary to put aside fixed patterns of thinking, inherited from the past, to consider afresh our morals, and our system of values in general.

(Abalkin, 1990 p. 9)

This has been a recurring theme, appearing quite often in the Soviet Parliament and government bodies, in the mass media, and in academic journals: it is argued that the general public in the Soviet Union is not prepared to accept and fully use markets.

For an accurate study of the validity of this argument for the Soviet Union, one must have an explicit comparison group (another country) and compare carefully between the countries the frequencies of public understandings, values, attitudes, and behaviors relating to markets. People everywhere are, to some extent or with some frequency, resistant to market solutions, and when the differences in frequencies across countries are not total the casual observer of people cannot be expected to keep an accurate count. The importance of having a comparison or control group in research is of course well known, and the history of science shows many examples of carefully controlled studies overturning formerly "unassailable" theories.

We have undertaken surveys of randomly selected individuals in the Soviet Union and

*Shiller is the Stanley B. Resor Professor of Economics, Yale University, New Haven, CT 06520; Boycko is an economist at the Institute of World Economy and International Relations, U.S.S.R. Academy of Sciences, Profsoyuznaya 23, Moscow 117869; Korobov is a sociologist at the Institute for Sociology, U.S.S.R. Academy of Sciences, Krzizanovskogo 24/35 b. 5, Moscow 117259. The authors are grateful to Robert Abelson, Sergei Aukuzionek, Revold Entov, Martin Feldstein, Daniel Kahneman, Alvin Klevorick, William Mahota, Michael Montias, Andrey Poletaev, Thomas Richardson, Lawrence Summers, Richard Thaler, and participants at a seminar at the Cowles Foundation at Yale University for helpful comments. This paper was supported by the Institute of World Economy and International Relations of the U.S.S.R. Academy of Sciences, the Institute for Sociology of the U.S.S.R. Academy of Sciences, the Russell B. Sage Foundation, and the U.S. National Science Foundation. Any opinions are those of the authors and not necessarily those of their respective institutions.

in the United States with questions aimed at finding out about opinions concerning whether price changes are fair, attitudes toward income inequality, popular theories concerning the importance of incentives, inhibitions against exchange of money, envy or hostility toward business people and the rich, popular understandings of markets and speculation, understandings of the welfare effects of compensated price changes, and expectations of future government interference.

We use questions that are aimed at providing evidence on *fundamental* parameters of human behavior related to the success of free markets. Sometimes our questions are about aspects of everyday life that are not directly affected by government economic policies. Other questions are about basic economic intuition. Sociologists have noted that popular answers to such questions often differ substantially from the answers that would be suggested by the dominant ideology that is expressed by opinion leaders.¹

To our knowledge, there has never been a similar study that examines attitudes relevant to the functioning of free markets in these countries. There have, of course, been many recent opinion surveys in the Soviet Union, and a few of these ask questions that are relevant to the success of free markets. For example, one study (Yu. A. Levada, 1990) asked Soviets what kinds of changes they would consider to be important indicators of great improvement in the situation of the country. The authors of the study concluded that respondents tended to give high rank to general concepts like "bringing goods back on the counter" or stable prices and that "values that are asso-

ciated with economic and civil freedom have much fewer supporters" (Levada, 1990 p. 50).² The major surveys of attitudes of Soviets published in the United States, based on responses of Soviet emigres, were not directly interested in the potential for success of free markets; however, they did produce a few results tangentially relevant here. The Harvard Refugee Interview Project³ concluded from surveys in 1950-1951 that Soviet emigres tended to support government control of the economy, expressed a strong dedication to society over the individual, and reacted negatively to Western materialism. The Soviet Interview Project⁴ concluded from surveys in the early 1980's that Soviet emigres tended to support state control of medicine but not of agriculture and that most supported the right of workers to strike. However, there does not appear to be a lot more in these studies on attitudes toward free markets. No Western or Soviet study relevant to free markets that we know of has made explicit comparisons of Soviets with Westerners.

I. Questionnaire Design and Survey Methods

Our questionnaires included 36 questions, addressing various aspects of human behavior related to free markets.⁵ Some of our questions probed public opinion on certain issues, but mostly the respondents were asked to consider some imaginary situation that they might experience and to describe their behavior in, or judgment of, that situation.

Naturally, when evaluating responses there is always some doubt whether they

¹Nicholas Abercrombie et al. (1980 p. 141), after reviewing a variety of interview results, asserted that people "will often agree with dominant elements, especially when these are couched as abstract principles or refer to general situations, which is normally the case in interview surveys using standardised questionnaires, but will then accept deviant values when they themselves are directly involved or when these are expressed in concrete terms which correspond to everyday reality."

²For a summary of other relevant Soviet public-opinion research, see Hans Aage (1991).

³For an overview of the results of this project, see Raymond Bauer et al. (1957).

⁴For an overview of this project, see James Millar (1987).

⁵Original questionnaires in both English and Russian, as well as further information about the samples and statistical methods, are available from the Cowles Foundation, Yale University, as part of Discussion Paper No. 952, August 1990.

were really determined by the basic attitudes we are interested in and not by the specifics of a particular scenario. To develop confidence in our results, we usually asked a number of similar questions placed in different contexts (and sometimes even addressed to different subsamples). When there are similar responses to these questions, we feel that we have some grounds to generalize beyond the specifics of the particular situations. In a sense, it is the totality of all the questions asked that gives us more confidence in the results reported below.

Still, we think that the evidence is mostly suggestive, not assertive. In some cases, the results just indicate that certain types of beliefs about the Soviets and Americans are at odds with the evidence that we have. Although we do not claim to settle the issues here, we think that our results do provide some substantial evidence.

When designing the questions, we tried to do our best to make them equally comprehensible to the Soviet and the American respondents. For that, first of all, we took great care in selecting our scenarios of imaginary situations that would possibly make the same sense for both audiences, despite the very different institutional environments that they generally face. For instance, one of our questions (B2) described a price increase at a flower market due to soaring demand on the eve of a holiday. This is a rare instance of a temporary price increase that the Soviets are quite familiar with. Similarly, when comparing price and nonprice rationing methods (question C4), we used gasoline as our example because Americans may still remember President Carter's standby gasoline rationing plan of 1979, or the odd-day/even-day gasoline rationing scheme actually imposed by some eastern states then.

Second, we put a lot of effort into selecting suitable wordings, so that the questions would sound as much alike as possible in the two languages. Originally the questionnaire was developed in English, but then we made several rounds of translating it into Russian and back, each time adjusting the wordings where appropriate. We also usually said something like "5 percent" rather

than "a little" to reduce further ambiguities in translation.⁶

The survey was conducted by means of telephone interviews with randomly selected individuals of 18 years of age or older. We documented responses from 391 residents of Moscow and 361 residents of the greater New York City consolidated metropolitan statistical area. The 36 questions were subdivided into three parts (designated A, B, and C in the question numbers), and each respondent was asked to answer only one part consisting of 12 questions. We were able to document about 120–130 responses per question in each country. The two samples were generally representative of their underlying populations and also rather close to each other in terms of basic characteristics: average age was 45 in the Soviet Union and 42 in the United States; 60 percent of U.S.S.R. respondents and 58 percent of U.S. respondents were female; 50 percent of U.S.S.R. respondents and 66 percent of U.S. respondents had attended some college. In both countries, those who agreed to participate in the survey were perhaps a little more articulate and informed than average for their respective populations, but it is our impression that as a result they generally had no difficulty understanding the questions.

The closeness of characteristics of the samples makes it generally possible to attribute any differences that we find to genuine differences between Soviets and Americans and not to differences in the composition of our samples.⁷ However, we

⁶In an independent evaluation of our translation, William Mahota, Professor of Slavic Languages and Literature, Yale University, wrote, "I have closely compared the Russian and English versions of Shiller, Boycko, and Korobov's survey of attitudes toward economic problems, and found that the language of the two versions corresponds virtually exactly." (See the earlier version of this paper: Shiller et al., 1990.)

⁷With sample sizes of a little over 100, the standard error of an estimated proportion is just under 5 percent if the estimated proportion is 50 percent; it is 4 percent if the estimated proportion is 25 percent or 75 percent; and it is 3 percent if the sample estimated proportion is 10 percent or 90 percent. Thus, for exam-

have also carried out probit regressions that allow us to evaluate the statistical significance of the intercountry differences when other observable characteristics are controlled for. When presenting our results below, we report *t* statistics of the coefficient of the country dummy variable in a probit regression. All estimated equations for each question had a constant term and the same standard set of right-hand-side predictors: namely, dummies for country, sex, and rural origin and also respondent's age and education level (based on an index from 1 to 6, with 1 representing "did not finish high school" and 6 indicating "finished graduate school").

There are somewhat fewer telephones per household in Moscow. At the end of 1988, there were 2.70 million telephones in private apartments in Moscow; at the same time, there were 3.05 million private apartments, implying 89 telephones per 100 apartments (*Moskva v Tsifrach*, 1989). In 1990, an estimated 93 percent of all households in the New York consolidated metropolitan statistical area had telephones. Only 61 percent of New York households had listed phones,⁸ but with random-digit dialing, nonlisting does not affect results.

An obvious criticism of our samples is that Moscow is probably not representative of the Soviet Union at large; the people there may be a little more educated or aware of economic issues. However, New York City, sometimes referred to as the business and financial "capital" of the United States, may also be populated by those who are more "advanced" in their attitudes toward markets than the rest of the country, so that the intracountry bias is possibly in the same direction. Even if this argument is not entirely convincing, we feel that a comparison between the two cities is quite meaningful by itself. The respondents in our two samples may represent the more

economically active and influential people in the two countries. Thus, our results may be more relevant to understanding economic events in the two countries than if we had taken a representative sample of everyone in the two countries.

II. Fairness of Price Changes

One important potential obstacle to the clearing of free markets is a popular feeling that price increases may be unfair. If sellers feel that they cannot raise their prices, then they will be forced to use nonprice rationing to distribute their goods, contrary to market principles.

It is widely believed in the Soviet Union (and possibly elsewhere) that the Soviet people, being for a long time accustomed to stable, government-sanctioned prices, will be characteristically reluctant to accept market prices. Consider the following statement of V. O. Rukavishnikov, a prominent Soviet sociologist:

...[T]he public attitude towards possible increases of prices of consumer goods that are in short supply is extremely negative, because this solution to the problem of the queues is likely to lead to a situation with lots of goods on the counters, with no queues, but with few people being able to buy the goods; 83.7 percent of the people surveyed are against this solution. [4.4 percent support it, and 11.9 percent did not answer.]⁹

(Rukavishnikov, 1989 p. 4)

Such a result may reflect general human behavior, not just Soviet behavior. In North American survey results, Daniel Kahneman et al. (1986) have also documented much resistance to price increases that were considered unfair.

For a meaningful evaluation of the attitudes toward free prices in the Soviet Union, it is useful to compare Soviets and Americans responding to identical questions in

ple, an estimated sample proportion of 25 percent has a 95-percent confidence interval of 17-33 percent.

⁸The U.S. data were provided courtesy of Survey Sampling, Inc., Fairfield, CT.

⁹The figures are based on about 5,000 responses sent to the popular magazine *Sobesednik* by its readers in September and October 1988.

identical contexts. We report several similar scenarios (inspired by Kahneman et al.), designed to address this issue:

B2. *On a holiday, when there is a great demand for flowers, their prices usually go up. Is it fair for flower sellers to raise their prices like this?*

Response	U.S.S.R.	U.S.A.	t [1 vs. 2] ¹⁰ (d.f.)
1) Yes	34%	32%	-0.89
2) No	66%	68%	(241)
	N: 131	119	

B11. *A small factory produces kitchen tables and sells them at \$200 each. There is so much demand for the tables that it cannot meet it fully. The factory decides to raise the price of its tables by \$20, when there was no change in the costs of producing tables. Is this fair?*

Response	U.S.S.R.	U.S.A.	t [1 vs. 2] (d.f.)
1) Yes	34%	30%	-0.71
2) No	66%	70%	(242)
	N: 131	120	

A9. *A new railway line makes travel between city and summer homes positioned along this rail line substantially easier. Accordingly, summer homes along this railway become more desirable. Is it fair if rents are raised on summer homes there?*

Response	U.S.S.R.	U.S.A.	t [1 vs. 2] (d.f.)
1) Yes	57%	61%	0.06
2) No	43%	39%	(199)
	N: 98	115	

The critical point here is that there is virtually no difference between U.S.S.R. and U.S. answers. In the first two scenarios, we

discover a tendency in *both* countries to report that price increases are unfair. In the third scenario,¹¹ in *both* countries most people think that price increases are fair. Here, our comparison-group methodology displays its full power. Notions of fairness are very situation-specific: flower sellers are unfair if they raise their prices, while landlords who do so in the circumstance described are usually not. Notions of fairness are *not* country-specific. The bottom line from all of this is that there is little foundation to the aforementioned claims that Soviets are *characteristically* resistant to unfair price increases.

We were able to expand our understanding of fairness by asking about the policy implications of the fairness judgments. After the question about flower sellers we asked:

B3. *Should the government introduce limits on the increase in prices of flowers, even if it might produce a shortage of flowers?*

Response	U.S.S.R.	U.S.A.	t [1 vs. 2] (d.f.)
1) Yes	54%	28%	-3.71
2) No	46%	72%	(229)
	N: 123	115	

After the question about the manufacturer of tables we asked:

B12. *Apart from fairness, should the factory have the **right** to raise the price in this situation?*

Response	U.S.S.R.	U.S.A.	t [1 vs. 2] (d.f.)
1) Yes	57%	59%	0.29
2) No	43%	41%	(227)
	N: 118	118	

¹⁰Throughout this article, the t statistic is from a probit regression, as described above. In brackets, we indicate the construction of the binary choice variable.

¹¹Perhaps more striking than the majority who think a rent increase is fair is that Americans were more ready to provide a definite opinion; the response rates were as follows: U.S.S.R. = 75 percent; U.S.A. = 96 percent. This kind of difference was encountered rather often in our results, but it is of secondary importance for the purposes of this study.

In only one of these two questions, the first (B3), was there a significant difference between Soviet and American responses. Soviets are more likely to want to restrict the flower seller from raising prices, but both Soviets and Americans tend to agree that the manufacturer of tables has, in effect, the right to be "unfair." (The answers to the second question (B12) show that, in both countries, beliefs that something is unfair need not translate into an opinion that something should be illegal.)

Another perspective on the fairness issue can be gained by posing a question without the word "fair," but asking whether an action is "moral." Here, we have changed the context of the question to a price increase between sale and resale, raising the issue of profiteering:

C10. *A small merchant company buys vegetables from some rural people, brings the vegetables to the city, and sells them, making from this a large profit. The company honestly and openly tells the rural people what it is doing, and these people freely sell the company the vegetables at the agreed price. Is this behavior of the company, making large profits using the rural people, acceptable from a moral point of view?*

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 2] (d.f.)
1) Yes	49%	59%	0.52
2) No	51%	41%	(218)
	N: 120	116	

Again, the Soviets are not dramatically more concerned with profiteering, and this difference is not statistically significant.

We wanted to learn whether people would impose on themselves the hardships caused by rationing of quantities, and so we asked:

C4. *Suppose that the government wishes to reduce consumption of gasoline. They propose two methods of attaining this goal. First, the government could prohibit gas stations from selling, for example, more than five gallons to one person. Second, the government could put a tax on gasoline, and prices of gasoline*

would go up. From your point of view, which of these methods is better?

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 2] (d.f.)
1) First	43%	36%	-1.28
2) Second	57%	64%	(196)
	N: 104	109	

Now, neither the Soviets nor the Americans tend to think that it is a good idea to force people to buy gasoline in small quantities. The Americans were only slightly less likely to favor the rationing solution.

Overall, the reported evidence suggests that there is actually little ground to believe that the Soviets are characteristically more hostile toward free-market prices. The strong opposition to price reform (implying price increases) that undoubtedly exists in the Soviet Union should not be attributed to peculiarities of national character; rather, the economic and political interests should be given more weight. Obviously, by setting prices free, central planners will lose an important instrument of control over the enterprises as well as some arbitrage opportunities that result from disequilibrium pricing. (For additional evidence on attitudes toward price changes, see the response to question B6 in Section VII and questions C6 and B10 in Section VIII.)

III. Attitudes Toward Income Inequality

Popular notions of fairness are essentially related to attitudes toward inequality. Given the history of Communist ideology, it would seem that Soviet citizens might be more intolerant of inequalities of income and wealth. Of course, "from each according to his abilities, to each according to his needs" has long been a Communist slogan. With the reputation of the United States as the most capitalist country, it would seem that American citizens might be much more tolerant of inequalities of income and wealth. However, we found no evidence to support such a notion.

One question, designed to see whether people would object to pro-market reforms

because of envy of those people who would succeed under such reforms, found that the *Americans* were the most resistant:

A4. *Suppose the government wants to undertake a reform to improve the productivity of the economy. As a result, everyone will be better off, but the improvement in life will not affect people equally. A million people (people who respond energetically to the incentives in the plan and people with certain skills) will see their incomes triple while everyone else will see only a tiny income increase, about 1 percent. Would you support the plan?*

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 2] (<i>d.f.</i>)
1) Yes	55%	38%	-2.07
2) No	45%	64%	(199)
	N: 114	99	

The plan described makes everyone better off, so any objections would have to be motivated by the relative inequality created by the plan. Only about half of the Soviet respondents supported the plan, but even fewer of the U.S. respondents responded that way.

Another way to quantify attitudes toward income inequality is to ask respondents about how they would tax inheritances of the rich:

A10. *In your opinion, what inheritance tax rate for really wealthy people do you think we should have? A tax rate of 0 percent means that they can pass all of their wealth to their children, making them as rich as their parents. A rate of 50 percent means that they can pass half to their children. A rate of 100 percent means that they can pass none at all to their children.*

Rate	U.S.S.R.	U.S.A.
Mean	39%	37%
Median	34%	30%
	N: 99	107

There was virtually no difference between the Soviet and American answers.

IV. Popular Theories about the Importance of Incentives

One theory to explain the slowness of the Soviet Union to implement a market system is that people there do not believe in one of its alleged principal advantages: the incentives that the system creates for hard work. The Soviets are reputed not to think that most people are basically motivated for personal gain and to believe instead that people work better if they are in a social context that makes their work personally meaningful to them.

When our respondents were asked directly about this, it turned out that there was very little difference between the Soviet and American responses.¹²

A1. *Do you think that people work better if their pay is directly tied to the quantity and quality of their work?*

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 2] (<i>d.f.</i>)
1) Yes	90%	86%	-1.05
2) No	10%	14%	(226)
	N: 121	119	

We asked much the same question in a different way, in terms of the important qualities of managers:

C3. *Which of the following qualities is more important for the manager of a company?* [Response choices: 1) *The manager must show good will in his relation to workers and win their friendship;* 2) *The manager must be a strict enforcer of work discipline, giving*

¹²An earlier survey (Tom W. Smith, 1989) allows comparisons among seven different countries, including one socialist country (Hungary), in respondent's answers to a similar question. Respondents were asked how much they agreed with the statement "financial incentives are needed if people are to work hard." Of U.S. respondents, 68 percent agreed or strongly agreed; of Hungarian respondents 70 percent agreed or strongly agreed. In another survey in the Soviet Union (Yu. A. Levada, 1990) only 40 percent of a nationally representative urban sample agreed with the strongly worded statement "without big differences in labor remuneration there will be no incentives to good work."

incentives to hard workers and punishing laggards.]

Response	U.S.S.R.	U.S.A.	$t[1 \text{ vs. } 2]$ (d.f.)
1	33%	49%	2.65 (204)
2	68%	51%	
	N: 112	109	

Again, it is the Soviets, not the Americans, who tend to believe in strict managers.

We also asked our respondents if they had heard about the capitalist theory that, because of the importance of incentives, income inequality is a necessary evil:

A2. Some have expressed the following: "It's too bad that some people are poor while others are rich. But we can't fix that: if the government were to make sure that everyone had the same income, we would all be poor, since no one would have any material incentive to work hard." Have you heard such a theory or not? If yes, then how often?

Response	U.S.S.R.	U.S.A.	$t[(1+2) \text{ vs. } 3]$ (d.f.)
1) Often	38%	7%	-4.89
2) Once or twice	39%	38%	(231)
3) Never heard it	23%	55%	
	N: 125	120	

Surprisingly, the Soviet respondents were more familiar with this theory than their U.S. counterparts, perhaps due to current extensive discussions of this and related subjects in the Soviet mass media.

A3. Do you yourself personally agree with this theory?

Response	U.S.S.R.	U.S.A.	$t[1 \text{ vs. } 2]$ (d.f.)
1) Yes	41%	38%	-0.48
2) No	59%	62%	(213)
	N: 110	116	

Neither country seems to like this theory a lot, but the opposition to the theory is weaker among our respondents in the Soviet Union. It is the American responses that are more surprising here. Agreement with this theory is not actually contrary to Communist theory of the past 20 or so years. Alistair McAuley (1980 p. 242), in a survey of Soviet academic economists and lawyers, concludes that "most Soviet economists appear to advocate what one might call a meritocratic structure of wages."¹³

V. Resistance to Exchange of Money

The essence of a market system is the ability of persons to secure the things they want by the voluntary and unrestricted exchange of money. Such "creative" exchanges of money are quite different from the exchanges of money that might be sanctioned by a government agency that certifies that the transaction is fair and equitable. We hypothesized that considerations of fairness, equity, and friendship might inhibit such exchanges relatively more in the Soviet Union.

The charging of interest to others for a loan is a practice that has been censured as immoral since ancient times, but of course certain forms of interest payments have legal sanction in both the Soviet Union and the United States today. We sought to abstract from the current legal environment by describing a hypothetical situation between friends:

A7. Suppose you have agreed to lend a friend some money for six months, so that he will not miss a good opportunity to buy a summer home. Suppose banks are offering interest rates of 3 percent per year. Would you charge him interest on the loan?

¹³In Smith's survey, it was found that 25 percent of Hungarian and 31 percent of U.S. respondents either agreed or strongly agreed with the statement "large differences in income are necessary for national prosperity (Smith, 1989 p. 70).

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 2] (d.f.)
1) Yes	6%	29%	4.27
2) No	94%	71%	(215)
	N: 117	111	

The difference here is quite substantial: about five times as many U.S. respondents answered "yes," compared to their Soviet counterparts. Although most people in both countries said that they would not charge a friend interest, we interpret these results as implying that there is a much bigger minority in the United States who are accustomed to an exchange of money as a solution to everyday problems.

Still, it is not entirely clear that the difference reported is truly attitudinal, and not institutional. Even though the question specifies the rate of interest at 3 percent, U.S. respondents are more familiar with high interest rates and may therefore have learned in the past that lending money to a friend at zero interest can be costly. We sought, therefore, to find a question that is relatively unrelated to past market experience. We asked:

A8. *If you went on a vacation with friends and there were a lot of shared expenses, would there be a careful accounting of who spent what and a settling of accounts afterwards?*

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 2] (d.f.)
1) Yes	30%	47%	2.66
2) No	70%	53%	(221)
	N: 116	118	

Here again is some evidence that U.S. respondents are rather more accustomed to an exchange of money, although the difference is less striking than with the previous question about charging interest.

Another question that would appear to abstract from any different experience with market solutions in the situation described is the following:

B7. *You are standing in a long line to buy*

something. You see that someone comes to the line and is very distressed that the line is so long, saying he is in a great hurry and absolutely must make this purchase. A person at the front of the line offers to let him take his place in line for \$10.00. Would you be annoyed at this deal even though it won't cause you to wait any longer?

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 2] (d.f.)
1) Yes	69%	44%	-3.61
2) No	31%	56%	(240)
	N: 132	117	

Clearly, the Soviet respondents showed substantially more annoyance at the deal described than did the Americans. This annoyance is noteworthy, since the deal apparently is helping a distressed person and since the deal harms no one else. Such annoyance at harmless interruptions in line has been noted before (see Jon Elster, 1989).

As before, the difference in responses may be attributed to the specifics of economic conditions in the two countries. Currently, the queues constitute a major concern for the Soviet consumer, and he has ample reason to be quite touchy in this respect.

When evaluating responses to all three questions in this section taken together, a common explanation looks at least as persuasive as several specific ones. Therefore, we conclude that there is some evidence that the Soviets are, to a certain extent, less willing to accept exchange of money as a solution to their problems. (For supplementary evidence on these issues, see questions C1, B4, and A5 in Section VI.)

VI. Negative Attitudes Toward Business

Many scholars have claimed that the Russian people have a long-standing aversion to business and dislike of businessmen. Alexander Gerschenkron (1962 p. 60) wrote that "There is no doubt that throughout most of the nineteenth century a grave opprobrium attached to the entrepreneurial

activities in Russia Divorced from the peasantry, the entrepreneurs remained despised by the intelligentsia." The idea is commonplace that the Communist revolution may have had its roots partly in such feelings. We sought to find whether there is evidence that such feelings today really set Soviet citizens apart from their U.S. counterparts.

We sought first to find whether people in the two countries feel that they would be esteemed by their relatives and friends if they were successful in business:

C1. Suppose that as a result of successful business dealings you unexpectedly became rich. How do you imagine it would be received by your relatives at a holiday family gathering? Would they congratulate you and show great interest, or would they be judgmental and contemptuous? [Response choices: 1) They would show interest, would congratulate; 2) They would be judgmental and contemptuous; 3) They would be quiet, indifferent.]

Response	U.S.S.R.	U.S.A.	t[1 vs. (2+3)] (d.f.)
1	72%	92%	2.08
2	12%	6%	(194)
3	16%	3%	
N: 113		117	

The Americans get greater support from their relatives and friends, though most of the Soviets expect congratulations.

C9. Do you think that, if you worked independently today as a businessman and received profit, your friends and acquaintances would respect you less and not treat you as you deserve?

Response	U.S.S.R.	U.S.A.	t[1 vs. 2] (d.f.)
1) Yes	19%	4%	-3.04
2) No	81%	96%	(216)
N: 115		120	

This evidence suggests that on the whole

neither country lacks respect for businessmen, but there is less respect for them in the Soviet Union.

A somewhat different attitude toward business that we wished to explore is whether people relish the prospect of showing off their wealth, and whether or not that helps them find good friends:

C2. If you ever became rich, would you really like to spend some of the money by purchasing really fashionable clothes, expensive cars, or other extravagant items that make an impression on people?

Response	U.S.S.R.	U.S.A.	t[1 vs. 2] (d.f.)
1) Yes	35%	50%	1.60
2) No	65%	50%	(217)
N: 115		120	

These responses may be interpreted as indicating that the Americans find the life of a successful businessman more appealing or want to show off a bit more. However, this may just be the result of their better circumstances. Levels of aspiration are affected by the standards of one's peers and are raised by a sense of accomplishment or success; this point has been stressed by psychologists (see Kurt Lewin et al., 1944). One may argue also that the Soviets, with a substantially lower standard of living, simply have more immediate concerns on their minds than thinking about what to do when they become rich. They may not have found it worthwhile to expend the costs of collecting information about luxury goods.

A way of getting at attitudes toward success in business without mentioning specific purchases is to make people choose between a general notion of success in business or in some other arena of life:

B4. Which of the following achievements would please you more? [Response choices: 1) You win fortune without fame; you make enough money through successful business dealings so that you can live very comfortably

for the rest of your life; 2) You win fame without fortune: for example you win a medal at the Olympics or you become a respected journalist or scholar.]

Response	U.S.S.R.	U.S.A.	$t[1 \text{ vs. } 2]$ (d.f.)
1	65%	54%	-1.47 (201)
2	35%	46%	
N: 92		117	

Although the U.S. respondents answered the question much more freely (response rates: U.S.S.R. = 67 percent; U.S.A. = 98 percent), of those who did answer the Soviets were relatively more attracted by wealth.

A5. *Is it important to you that your work benefits the country, and is not just to make money? Is it very important, somewhat important, or not important?* [Response choices: 1) Very important; 2) Somewhat important; 3) Not important.]

Response	U.S.S.R.	U.S.A.	$t[(1+2) \text{ vs. } 3]$ (d.f.)
1	69%	40%	-2.25
2	25%	45%	(235)
3	6%	15%	
N: 130		119	

The U.S. respondents are more for the money here, though of course we could also interpret the results as indicating that they feel freer to *admit* this.¹⁴

Yet another way to get at attitudes toward business success is to try to elicit from respondents their prejudices against businessmen:

C11. *Do you think that it is likely to be difficult to make friends with people who have*

their own business (individual or small corporation) and are trying to make a profit?

Response	U.S.S.R.	U.S.A.	$t[1 \text{ vs. } 2]$ (d.f.)
1) Yes	51%	20%	-4.65
2) No	50%	80%	(214)
N: 111		121	

On this question, Soviets are much less sanguine about businessmen than are the Americans.

C5. *Do you think that those who try to make a lot of money will often turn out to be not very honest people?*

Response	U.S.S.R.	U.S.A.	$t[1 \text{ vs. } 2]$ (d.f.)
1) Yes	59%	39%	-2.23
2) No	41%	62%	(214)
N: 114		117	

Indeed, relatively more Soviets do tend to expect businessmen to be less honest.

These last two questions show that U.S.S.R. respondents attach negative prejudices toward businessmen; but a caveat is in order. When evaluating these prejudices, it is important to keep in mind that many Soviets have never met a businessman in an informal situation, to say nothing of knowing one well. Their answers may be determined by what they read or hear, not by personal experience.

Still, the prejudices that Soviets have today are probably obstacles toward development of business enterprises. The questions in this section, which have various interpretations individually, tend generally to support the notion that Soviets indeed display a somewhat less warm attitude toward business and may be less interested in business careers.

It should of course be borne in mind that the differences we found were often value differences, differences in what each person

¹⁴Bauer et al. (1957 p. 128) concluded from the Harvard Refugee Interview Project that Soviet emigres felt that "we [Westerners] are lacking in spiritual and cultural values, in altruism, in dedication to society."

wants in his or her own life. Perhaps economists should not argue over them or be concerned about them.

VII. Perceptions of Speculation

Many barriers to free market activity are supported in the Soviet Union on the ground that these activities represent "speculation." Unfortunately, the term "speculation" has a wide range of meanings. Sometimes the term "speculation" in the Soviet Union refers to activities that consist of taking (in effect stealing) goods intended by the government for some people and selling these at a profit to others. To what extent such activities are immoral when they are already illegal is not our concern here. We are concerned instead with the ultimate harm that is thought to follow from allowing forms of "speculation" that are legal in capitalist countries.

Soviet opposition to such speculation might come about as a result of opinions that speculative price increases are unfair, or as a result of opposition to income inequalities that might result from allowing people to speculate, or from the anti-business sentiments that we discussed in the preceding section. However, we have yet to explore a separate issue: whether speculation is viewed as disruptive in that it creates excess price volatility or shortages. Such a view would further justify laws against speculation.

B6. *If the price of coffee on the world market suddenly increased by 30 percent, what do you think is likely to be the blame?* [Response choices: 1) *Interventions of some government*; 2) *Such things as bad harvest in Brazil or unexpected changes in demand*; 3) *Speculators' efforts to raise prices.*]

Response	U.S.S.R.	U.S.A.	$t[3 \text{ vs. } (1+2)]$ (d.f.)
1	17%	13%	-2.93
2	51%	36%	(212)
3	32%	51%	
N:	109	111	

Surprisingly, the Americans were more likely to hold speculators responsible. To put this result into proper perspective, it is worthwhile to note that currently in the Soviet Union the "speculators" are vehemently blamed by the government and certain populist movements for "aggravating shortages" and bringing about price increases. The general public seems to be more skeptical about speculators' capabilities.

This finding was further confirmed by responses to another question that addressed the issue of speculation more directly:

C8. *Grain traders in capitalist countries sometimes hold grain without selling it, putting it in temporary storage in anticipation of higher prices later. Do you think this "speculation" will cause more frequent shortages of flour, bread, and other grain products? Or will it cause such shortages to become rarer?* [Response choices: 1) Shortages more common; 2) Shortages less common; 3) No effect on shortages.]

Response	U.S.S.R.	U.S.A.	$t[1 \text{ vs. } (2+3)]$ (d.f.)
1	45%	66%	1.54
2	31%	26%	(172)
3	24%	8%	
N:	110	112	

Thus, it is true that Soviets tend to blame speculators for shortages, but the Americans do so even more.

Overall, the present survey did not provide evidence that Americans were any more enlightened in their understanding of the functioning of free markets. (For complementary evidence on attitudes toward "profiteering," see question C10 in Section II.)

VIII. Understandings of Compensated Price Changes

At the time this paper was being written (June 1990), there was a heated debate going on in the Soviet Union on about whether

the public would tolerate the compensated increase in the price of bread and other grain products suggested by the Ryzhkov government. While the opinions expressed undoubtedly were heavily motivated by political issues at stake, it was rather disconcerting to hear repeated assertions that a fully compensated price increase was unacceptable because it would adversely affect the standard of living.

Our survey, completed just before the Ryzhkov government put forward its proposal, directly addressed the issue of a compensated price increase:

C6. *Suppose the price of electricity rises four-fold, from 10 cents per kilowatt hour to 40 cents per kilowatt hour. No other prices change. Suppose also that at the same time your monthly income increases by exactly enough to pay for the extra cost of electricity without cutting back on any of your other expenditures. Please evaluate how your overall material well-being has changed. Would you consider your situation: 1) Somewhat better off; 2) Exactly the same; 3) Somewhat worse off?*

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 3] (d.f.)
1	9%	3%	-2.63
2	77%	63%	(64)
3	14%	34%	
N:	120	121	

Much to our surprise, the responses are consistent with the hypothesis that the Soviets had a better understanding than the Americans that such a change either makes no difference in well-being or improves it.

A related question was asked, outlining a scenario of a compensated increase in the aggregate level of prices:

B10. *Suppose that economists have come to the conclusion that we could substantially improve our standard of living in the next year if we would be willing to accept a 30-per-*

cent inflation rate (increase in the prices of goods by 30 percent). This would mean that our incomes would rise by more than 30 percent. Then we could buy more goods at the new higher prices. Would you support such a proposal?

Response	U.S.S.R.	U.S.A.	<i>t</i> [1 vs. 2] (d.f.)
1) Yes	47%	28%	-3.17
2) No	53%	72%	(226)
N:	118	115	

In accordance with the previous finding, the Soviets proved to be more tolerant of inflation (that was not eroding their incomes) than Americans. (The different answers might also be affected by a difference in the way economists are viewed in the two countries, but the direction of this particular bias is unclear to the present authors.)

IX. Expectations of Possible Future Government Interference

Much recent economic theorizing has emphasized that economic agents respond not only to current government policy but also to anticipated future government policy. Unless the government can commit itself to a new policy, economic agents may, in making long-term decisions, assume that an older policy regime is still relevant. Thus, another impediment to the development of markets in the Soviet Union may be the lingering effect of a memory of the old regime and a feeling that some of its features may be back in the future.

We did find a substantial difference that relates to expectations that the government might usurp the investments people make in private businesses:

C7. *How likely do you think it is that in the next few years the government will, in some way, nationalize (that is, take over) most private businesses with little or no compensation to the owners? Is such nationalization quite likely, possible, unlikely, or impossible?*

[Response choices: 1) Quite likely; 2) Possible; 3) Unlikely; 4) Impossible.]

Response	U.S.S.R.	U.S.A.	$t[(1+2) \text{ vs. } (3+4)]$ (d.f.)
1	20%	5%	-6.37
2	40%	11%	(214)
3	29%	53%	
4	11%	31%	
N: 114		118	

From the Soviet answers here, it would appear that there should be substantial reservations about investing too many resources in cooperatives.

We thought also that Soviets would have a rather weak incentive to save, because of a feeling of insecurity of their savings. After our survey, the Pavlov government actually imposed restrictions on the amount one can withdraw from bank accounts, but our Soviet respondents did not show strong anticipation of such government interference with savings:

B8. *How likely is it, from your point of view, that the government in the next few years will take measures, in one way or another, to prevent those who have saved a great deal from making use of their savings? Is it quite likely, possible, unlikely, or impossible that the government will do this?* [Response choices: 1) Quite likely; 2) Possible; 3) Unlikely; 4) Impossible.]

Response	U.S.S.R.	U.S.A.	$t[(1+2) \text{ vs. } (3+4)]$ (d.f.)
1	17%	15%	-1.34
2	44%	37%	(221)
3	21%	39%	
4	19%	9%	
N: 112		117	

There is some evidence of less confidence of the Soviets, best visible in the "(1+2)/(3+4)" proportion: 61/39 for the Soviet Union; 52/48 for the United States. This difference is not statistically significant, however, and it is well below our prior expectations. Perhaps Americans were thinking of pressures

on the federal government from the deficit and of actions the government might take, such as renegeing on their savings-and-loan obligations, or changing the social-security system or medicare system.

X. Interpretation and Conclusion

It is useful to consider the results of our survey in the context of a specific example of the kinds of things that go wrong in the Soviet Union today. There has been recently a shortage of soap in the Soviet Union. Why has this happened? Why aren't many people setting up cottage industries to manufacture soap (a product that is extremely simple to produce, as industrial commodities go)? Why isn't someone buying soap from available sources and distributing it around the Soviet Union? In short, why aren't the fledgling entrepreneurs in the Soviet Union dealing with the shortage problem?

On one level, the answer is that it is difficult for an enterprise to obtain special permission to start manufacturing or distributing soap. However, on a deeper level, one might ask, why on earth should one need any permission to manufacture and distribute soap in a country that is suffering so much from a shortage of soap? Why should there be any public support for regulators who deny permission for new cooperatives to start to produce or distribute soap?¹⁵

In this paper, we have investigated a number of possible theories to explain why people might feel that the laws should prevent private forces from dealing with the shortage of soap and, hence, why potential private producers of soap might not even try to get the necessary permission or might fear social pressure against such an enterprise. One theory is that people are concerned with fairness of prices, and they would not want to allow prices of soap to

¹⁵Of course, delays to give regulators time to assess the environmental impact of a new manufacturing enterprise may well receive public support, and this particular extreme shortage would likely be viewed as temporary.

rise to reflect the scarcity. Another theory is that people are concerned with the income inequality that might be created if a few entrepreneurs make a lot of money selling soap. Yet another theory is that people do not perceive that the production of soap would be much more effective in a situation where the laws permitted incentives for private production.

While survey questionnaire results do not constitute definitive proof about social attitudes, none of the above-mentioned theories for the relative lack of success of free markets in the Soviet Union has any support in our results. In this study, Soviets appear to be no more concerned with fairness of prices than are U.S. citizens. Further, Soviets appear to be no more concerned with income inequality, and they appear to have the same or even stronger appreciation of the importance of incentives.

Other theories are that there is simply a resistance toward the exchange of money among individuals, as contradicting a sense of regularity in contractual relations, that there is a general lack of interest in starting and running businesses, or that there is a fear that the government will do something in the future to remove the wealth of successful people. We did find some evidence that there is such a resistance toward exchange of money and less warm attitudes toward business; we found also that there may be more of a concern that the government may later nationalize private enterprises. This evidence is of great concern in assessing the long-run outlook for the level of prosperity of the Soviet Union. Still, these differences do not seem so large as to be considered the prime suspects in the annoyingly tangible and immediate problems today, like that of the soap shortage.

Because the differences between the Soviet Union and the United States we found were often small or nonexistent, we feel that perhaps too much prominence has been given in discussions of the transition to a market system in the Soviet Union today to the differences between Soviets and people in market economies. The pressing and immediate problems faced in the Soviet Union

today may be instead political and institutional in nature. When a country inherits an institutional and political framework that has been anti-market, it serves certain entrenched interests in that country to resist change. Thus, individuals who benefit from the present system may make public appeals to fairness, abhorrence of income inequality, and other attitudes to try to stop change. Alternatively, well-meaning Soviet government planners may feel constrained by their incorrect belief that the Soviet public is much more concerned with fairness or income inequality than are the publics in capitalist countries.

Indeed, we have found here that Soviets are concerned with fair prices and with income inequality, so that these concerns might help prevent change to a market economy. However, at the same time, these concerns appear to be little different among Americans. Perhaps Americans would resist perestroika with as much vigor if they inherited the Soviet political and institutional system.

In considering the remarkable similarity between many of the Soviet and American results, it may be well to recall a much earlier interpretation of comparison of Americans with Europeans. Alexis de Tocqueville, in his 1850 book *Democracy in America*, wrote that the "love of money" found among Americans was not a consequence of their national character, but was the natural consequence of a stable system organized around private initiative:

What I say about the Americans applies to almost all men nowadays. Variety is disappearing from the human race; the same ways of behaving, thinking, and feeling are found in every corner of the world. This is not only because nations are more in touch with each other and able to copy each other more closely, but because the men of each country, more and more completely discarding the ideas and feelings peculiar to one caste, profession, or family, are all at the same getting closer to what is essential in man, and that is everywhere the same. In that way they grow alike, even with-

out imitating each other. One could compare them to travelers dispersed through a huge forest, all the tracks in which lead to the same point. If all at the same time notice where the central point is and direct their steps thither, they will unconsciously draw nearer together without either seeking, or seeing, or knowing each other, and in the end will be surprised to find that they have all assembled at the same place. (p. 591)

Price Distortion and Shortage Deformation, or What Happened to the Soap?

By MARTIN L. WEITZMAN*

The model of this paper generalizes the classical theory of consumer behavior to the more general case of prices that are not necessarily market-clearing. Suppose that, in addition to the money cost, some sort of search, waiting, or other quasi-fixed "effort-cost" is needed to obtain goods. The presence of this quasi-fixed cost element will trigger an inventory policy. A shortage equilibrium occurs when effort costs are such that, in the corresponding inventory policy, the flow of desired consumption does not exceed the available supply flow. Stock hoarding, a critical phenomenon in the economics of shortage, emerges as a natural component of this model. A complete characterization of a stationary shortage equilibrium is given. Comparative statics and welfare analysis are performed. The dynamic transition between steady states is analyzed to give insight into the mechanics of how shortages develop. (JEL D50)

It is known, in a general way, that price distortions lead to shortages, queues, searching, hoarding, and so forth. Yet it seems fair to say that the exact mechanism integrating each main element of a "shortage syndrome," especially the stockpiling phenomenon, has not been clearly articulated.¹ The main aim of this paper is to provide a usable model of shortages by appropriately generalizing the classical theory

of consumer behavior to a situation where prices are not necessarily market-clearing. The model essentially consists of an equilibrium approach that combines inventory theory with demand theory.

A particularly vivid illustration of the phenomenon I have in mind is illustrated by recent Soviet experience in the consumer-goods market. Consider Soviet soap as a metaphorical example. The example is metaphorical because, while the shortage phenomenon in the consumer-goods market I seek to describe is quite general, the particular commodity most illustrative of the general phenomenon can vary.

Throughout most of 1989 (at the time this paper was written), there was virtually no soap available on the shelves of Soviet stores. When officials in charge of planning were asked about this problem, they acted embarrassed and annoyed. In newspaper articles and television talk shows, they explained repeatedly that production this year was actually up 10 percent over last year, which was itself 4 percent higher than the previous year. Furthermore, not only was production accelerated somewhat as this embarrassing shortage became evident, but more than \$8 million of valuable foreign exchange was spent on buying soap abroad. Finally, they pointed out that statistics of

*Department of Economics, Harvard University, Cambridge, MA 02138. This research was supported by a grant from the National Science Foundation.

¹Some models dealing with somewhat different aspects of this phenomenon are described in Janos Kornai and Jorgen Weibull (1978), Victor Polterovich (1983), Dale Stahl and Michael Alexeev (1985), Kent Osband (1989), and the references cited in these works. The case typically treated has the waiting-effort cost proportional to the amount of the good bought. This is equivalent to the assumption that people are limited to buying one small unit at a time and must wait in line anew for each small purchase that is made. (It is then a straightforward exercise to generalize to an "as if" market equilibrium where the "as if" price is the money price plus the appropriately normalized disutility of waiting-effort price.) I much prefer the opposite assumption: after waiting in line for a sufficiently long time, or happening upon the good, the customer can effectively buy as much as he wants. I think this is a more realistic assumption of the two extremes; additionally it leads naturally to an analysis of the key inventory-stock aspect of the problem.

per capita soap consumption show the Soviet Union to be not very far behind the advanced Western capitalist countries. All of this sounds quite believable; and on the whole Soviet citizens do not seem to be going unwashed.

The above story can be repeated for any number of commodities. Soviet leaders frequently characterize the economy as being in a "crisis situation" ("krizisnoye polozheniye"); but what, exactly, is the crisis? What is the appropriate model of causality leading from budget deficits and a monetary overhang to disorders in the consumer-goods markets? What is happening? What should be done?

To such questions no clear answers emerge. Some cite breakdowns in the distribution system. (Railroads seem particularly to be accused.) Others blame a "hoarding psychology" that causes panic buying and is somehow related to the deficit and monetary overhang. Theft by workers, sabotage, and speculation by cooperatives are also candidates. The officials seem unified only on promising increased production to meet the shortage and on calling for formation of committees to investigate formally the problem.

Some informal investigation reveals an interesting, if perhaps not unexpected, fact. Although few official figures are available, observations, conversations, and anecdotes suggest strongly that Soviet people are hoarding soap and other commodities in massive amounts. Significant parts of bathrooms, closets, hallways, and other areas have been given over to storage.

My aim is to model carefully the general process of "hoarding psychology," which is a fairly widespread occurrence in shortage situations, even if it is not typically so extreme as the above case. I believe the model has potential applications to a wide variety of situations where prices are stuck at "wrong" values for whatever reason. Thus, some conclusions may have relevance for malfunctioning markets in capitalist economies and may even help to understand certain features of "fixed-price" macroeconomics. It will be shown that hoarding psychology can be given a quite

rational economic interpretation and can be coherently analyzed within the appropriately extended framework of standard economic theory.

I. The Model

Suppose there are n goods in the economy, denoted $i = 1, 2, \dots, n$. For the sake of argument, all consumers are assumed to be identical. (Allowing consumers to be different would not affect the existence or general form of an equilibrium, but it would render less sharp the characterization of its properties.)

Each consumer has the same utility function of the form

$$(1) \quad U(\mathbf{d}) - V(e) - W(s).$$

In the above formula, $\mathbf{d} = (d_i)$ is the usual consumption n -vector. The variable e_i stands for the amount of "effort" required to obtain good i each time that it is obtained. Conceptually it is perhaps easiest to think of e_i as the time wait in line needed to buy good i . (There is a separate line for each good, and after waiting the required time,² the consumer can buy as much as desired.) However, e_i could more generally represent search effort of any sort expended to obtain the commodity. On the most abstract level, e_i is interpreted as the degree of difficulty in obtaining good i . If good i is obtained at frequency f_i , then the total effort (per unit time) expended on obtaining all goods³ is

$$(2) \quad e \equiv \sum f_i e_i.$$

While it is conceptually easiest to think of effort e_i as deterministic, there is no prob-

²Note that e_i represents the time wait in line, not the length of the line. If m people, each of whom stocks up amount s , are waiting in line and the total flow of goods into the store is d , then the time wait in line is $e = ms/d$.

³By writing disutility as a function of total effort, $V(e)$, I am implicitly assuming that the sum of a large number of fixed costs incurred at different times can, in effect, be smoothed.

lem with an interpretation that makes each e_i an independently distributed random variable so long as it is small relative to n . Then by the law of large numbers, e itself will be (almost) deterministic, equal to a weighted sum of the form (2), where e_i is now interpreted as the *expected* effort that must be spent on obtaining good i .

The variable s_i stands for the stock of good i that is purchased and must be stored when the good is obtained. The coefficient h_i represents the opportunity cost per unit of good i carried (per unit time). The magnitude of h_i would reflect such things as the opportunity cost of storage space i takes up (on shelves, in refrigerators, in warehouses, or whenever applicable), shrinkage, the cost of guarding, interest forgone, the inconvenience of hoarding, and so forth. Total storage cost is then

$$(3) \quad s \equiv \sum h_i s_i.$$

The representative consumer's utility function is assumed to be of the additively separable form (1). The first element $U(\mathbf{d})$ is just the traditional utility function of classical consumer theory, having all the usual properties. The function $V(e)$ represents the disutility of effort, while $W(s)$ is the disutility of storage. The underlying assumption in (1) of independence would appear not to be terribly restrictive, and perhaps even reasonable, in the present context. More general formulations could be treated but with some loss in crispness of results. It is assumed that $U(\mathbf{d})$ is smoothly concave, while $V(e)$ and $W(s)$ are smoothly convex.

The representative consumer faces fixed nominal prices $\mathbf{p} = (p_i)$ and is endowed with nominal money income I . Thus, the usual budget constraint

$$(4) \quad \mathbf{p}\mathbf{d} \leq I$$

holds.

Unlike the classical setup, however, in the situation here prices are not necessarily market-clearing.⁴ Quantities available per

capita are $\mathbf{q} = (q_i)$. Any feasible consumer demand must satisfy the additional constraints

$$(5) \quad \mathbf{d} \leq \mathbf{q}.$$

The supplementary constraints (5) distinguish the present model from classical consumer theory. In the classical case, in effect $q_i = \infty$ for all i , or else \mathbf{p} represents equilibrium prices that just exactly make demands \mathbf{d} equal to supplies \mathbf{q} . For the classical case, in effect there are no explicit constraints on consumer purchases other than the overall budget constraint (4). Here, the interesting case is when constraint (5) "bites" for some goods, representing inadequate supply at the fixed prices, presumably arising ultimately from production limitations.

The present formulation is sufficiently rich to cover a number of special situations of interest. For example, the price might be artificially repressed on only one or a few goods, which then become "deficit" compared to the bulk of commodities, which are market-clearing; or there could be a general deficit of commodities, meaning the prices of most goods are artificially low relative to incomes and availability. Also covered is the case in which the same good is available cheaply in limited amounts at state stores and simultaneously at market-clearing prices in private stores. Yet another situation covered with only slight modification of the present framework is that in which a given fixed vector of goods is to be allocated, so that consumers end up with the same final allocation of goods in any case, but for some given subset of (deficit) goods prices are frozen at below market-clearing levels, while for the remaining (available) goods, prices

⁴It is beyond the scope of this paper to speculate on why certain prices may be set at below market-clearing

levels in certain circumstances. Suffice it to note here that the practice is extremely widespread, and there is an extensive literature on many aspects of it. Governments are fearful of raising prices once they have become established, often with good reason because people do not like price increases. The present paper is limited to analyzing the effects of too low prices without delving deeply into the issue of why they are too low in the first place.

move freely to their competitive levels, which just clear the fixed supplies taking account of consumer income. Since $U(\mathbf{d})$ represents the familiar utility function of goods consumed, it automatically embodies the usual relations of complementarity, substitutability, diminishing returns, and whatever else might be considered relevant to the situation at hand.

II. Coefficient of Price Distortion

In what follows, it will be useful to have a quantitative measure of the degree to which values and prices are distorted in the economy under consideration. To that end, consider the following mathematical programming problem:

$$(6) \quad \max[U(\mathbf{d})]$$

subject to

$$(7) \quad \mathbf{d} \leq \mathbf{q}$$

$$(8) \quad \mathbf{p}\mathbf{d} \leq I.$$

The constrained optimization (6)–(8) is a classical resource-allocation problem. In the present context, it can be interpreted as a second-best problem in optimal rationing. Let the solution be

$$(9) \quad \mathbf{d} = \mathbf{d}^*.$$

Let λ be the shadow price of constraint (8). Without significant loss of generality, suppose that the marginal utility of income is positive or that $\lambda > 0$. [The marginal utility of an extra ruble is greater than zero, which means that constraint (7) is not so tight in every component that no goods are available to be bought on the margin. This would be guaranteed in theory if, for example, some of the goods were available in unlimited supply, or if prices on some of the goods were market clearing.] Then, it is not difficult to see that

$$(10) \quad \lambda = \min_i \left[\frac{U_i}{p_i} \right]$$

where

$$(11) \quad U_i \equiv \left. \frac{\partial U}{\partial d_i} \right|_{\mathbf{d} = \mathbf{d}^*}.$$

Necessary and sufficient conditions for an optimum are then

$$(12) \quad U_i > \lambda p_i \rightarrow d_i^* = q_i.$$

While λp_i represents the nominal price of an extra unit of good i (normalized so that the marginal utility of income is 1), U_i measures the actual value of an additional unit of good i , or what people would actually be willing to pay. In the present context, it is then natural to define the coefficient of value distortion or price distortion of good i (weighted by the amount of the good) as

$$(13) \quad \delta_i \equiv (U_i - \lambda p_i) d_i^*.$$

The coefficient δ_i measures the difference between the actual value of good i that might be consumed and the nominal price value, normalized in terms of utility. Therefore, δ_i is a measure of the degree of disequilibrium deviation from market-clearing of good i . If the logic of (13) is accepted, the appropriate measure of overall value or price distortion in the economy becomes

$$(14) \quad \delta \equiv \sum \delta_i.$$

The coefficient δ is a measure of the degree of overall disequilibrium in the economy.

III. The Basic Problem

The question now arises as to how the goods are actually distributed in the model economy, given the existence of constraints (4) and (5). As a point of departure, suppose that a state of chronic shortages exists in an orderly stationary equilibrium. That is, every consumer knows he must expend effort e_i to obtain good i and plans the appropriate inventory policy. After, in effect, paying the fixed waiting-time cost of e_i , the consumer chooses to buy and stock the amount s_i and run it down at the consumption flow rate d_i . This pattern is repeated at

frequency

$$(15) \quad f_i = \frac{d_i}{s_i}.$$

Furthermore, economy-wide this repetitive behavior is self-reinforcing.

Of course this description of shortage behavior as a regular steady-state equilibrium with recurrent sawtooth-patterned inventories is an abstraction. Shortage phenomena can be notoriously erratic. Nevertheless, treating a shortage economy as if it were in a stationary equilibrium yields important quantitative insights. Furthermore, it is a necessary first step to any analysis of dynamics. Actually, the methodological issues connected with modeling a shortage equilibrium do not seem fundamentally different from those involved in modeling a nonshortage equilibrium.

Consider the problem facing the typical consumer. Effort levels $\{e_i\} \geq 0$ are taken as given.⁵ Consumption flow levels $\{d_i\}$ and inventory stocks $\{s_i\}$ should be chosen to:

$$(16) \quad \underset{\{d_i, s_i\} \geq 0}{\text{maximize}} \left[U(\{d_i\}) - V \left(\sum e_i \left[\frac{d_i}{s_i} \right] \right) - W(\sum h_i s_i) \right]$$

subject to

$$(17) \quad \sum p_i d_i \leq I.$$

In what follows, I assume that the first-order necessary conditions for characterizing an optimum to the above problem [(16) and (17)] are also sufficient.⁶

⁵In equilibrium, $\{e_i\}$ will be like an implicit price that equilibrates the system, but each individual consumer will view $\{e_i\}$ as exogenously given.

⁶A variety of conditions would guarantee this result. Essentially, the inventory part is introducing an economy of scale into an otherwise convex problem. So long as the inventory nonconvexity effect can be bounded [e.g., by assuming that $\{e_i\}$ is small relative to the curvature of $U(\cdot)$], the necessary first-order conditions for (16)–(17) would remain sufficient. In this paper, I will not go further into the essentially technical and messy aspect of insuring that necessary conditions are

In the economy being modeled, the appropriate equilibrium concept is the following.

DEFINITION: A stationary shortage equilibrium is a set of $\{e_i, d_i, s_i\}$ satisfying the following three conditions:

$$(18) \quad \{d_i, s_i\} \text{ solves problem}$$

$$(16) \text{--}(17) \text{ for given } \{e_i\}$$

$$(19) \quad d_i \leq q_i \text{ for all } i$$

$$(20) \quad \text{if } d_i < q_i, \text{ then } e_i = 0.$$

The reader should feel satisfied, upon reflection, that conditions (18)–(20) represent the correct generalization of classical consumer equilibrium theory to the present context.⁷

It is not difficult to generalize the definition of a stationary shortage equilibrium to a situation with many nonidentical consumers having different utility functions and different incomes, nor is it difficult to prove existence using methods similar to those employed in the present paper. This route is not pursued in detail here simply because, as with most truly general equilibrium formulations, it is impossible to characterize sharply the properties of a solution without placing more structure on the model.

The following theorem completely characterizes a stationary shortage equilibrium.

sufficient for the given problem. I am indebted to Victor M. Polterovich for pointing out to me that some assumption needs to be made in order to presume that the necessary first-order conditions for a maximum of (16)–(17) are also sufficient in the present context.

⁷There is an implicit assumption behind definition (18)–(20) that at any instant in time consumers hold uniformly distributed stocks of good i , ranging from s_i to 0, and they arrive uniformly to market just as their stock of the good is depleted. This assumption could presumably be justified as the outcome of a dynamic optimizing process in which consumers satisfying the overtaking criterion always choose the line with the shortest wait and thereby force all waiting lines for the same good to have equal length in equilibrium.

THEOREM 1: *The unique stationary shortage equilibrium is the solution of the following equations.⁸*

$$(21) \quad d_i = d_i^*$$

$$(22) \quad s_i = \frac{\delta_i}{wh_i}$$

$$(23) \quad e_i = \frac{\delta_i^2}{vwh_id_i^*}$$

where

$$(24) \quad w \equiv W'(s)$$

is the marginal disutility of storage evaluated at $s (= \sum h_i s_i)$ satisfying

$$(25) \quad sW'(s) = \delta$$

while

$$(26) \quad v \equiv V'(e)$$

is the marginal disutility of effort evaluated at $e (= \sum f_i e_i)$ satisfying

$$(27) \quad eV'(e) = \delta.$$

PROOF:

In the optimization problem (16)–(17) that defines condition (18), let $\mu \geq 0$ be the shadow price multiplier for inequality (17). The corresponding necessary and, by assumption, sufficient first-order conditions for any $d, s \geq 0$ satisfying (17) to be the unique maximizer of (16) are, for all i ,

$$(28) \quad U_i - V'\left(\frac{e_i}{s_i}\right) = \mu p_i$$

$$(29) \quad V'\left(\frac{e_i d_i}{s_i^2}\right) = W'(h_i).$$

⁸ Conditions (21)–(27) are presented in the given sequence and form to facilitate their economic interpretation. From the strictly mathematical standpoint of presenting an algorithm that uniquely solves (18)–(20), it is preferable to think of the following order: first (21) defines $\{d_i\}$, then (25) defines s and (27) defines e , then (24) defines w and (26) defines v , then (22) defines $\{s_i\}$ and (23) defines $\{e_i\}$. Equations (25) and (27) have unique solutions in s and e , from the convexity of $V(e)$ and $W(s)$.

[Equation (29), rearranged, is the famous square-root law of inventory theory.]

The rest of the proof is essentially by inspection. Assignments (21)–(27) and the supplementary assignment

$$(30) \quad \mu = \lambda$$

are proposed as the solution of (18)–(20). Using conditions (4), (5), (12), and (13), it is straightforward to verify that the proposed solution, (21)–(27) and (30), does indeed satisfy (28), (29), (19), and (20).

With the shortage equilibrium expressed in the simple closed form (21)–(27), it is easy to perform comparative-static exercises.

Note from (22) that s_i is proportional to δ_i , while from (23) e_i is proportional to δ_i^2 . Thus, small shortages show themselves primarily in increased stock hoarding, with just very small increases in search activity. On the other hand, large shortages result in large inventories and very large waiting lines or search times. These observations suggest how shortages might evolve or devolve.

While from (23) effort per purchase is proportional to the square of the coefficient of price distortion, total effort is not. This is because, as waiting lines increase, the consumer reacts by buying bigger bundles less frequently. The total effort per unit time spent on obtaining good i is, from (15) and (21)–(23),

$$(31) \quad f_i e_i = \delta_i / v.$$

Substituting (31) and (22) into (13) yields, respectively,

$$(32) \quad U_i = \lambda p_i + v \frac{f_i e_i}{d_i}$$

$$(33) \quad U_i = \lambda p_i + w \frac{h_i s_i}{d_i}.$$

Thus, the difference between the intrinsic value of a good and its nominal price is made up by the effort expended per unit of the good to obtain it [equation (32)] and also by the cost expended per unit of the good to store it [equation (33)]. In shortage

equilibrium, the consumer ultimately gets what goods [equation (21)] he would have gotten under the optimal rationing scheme (6)–(8). However, from (32) and (33), it is the cost of nonproductive search and storage activity that raises the “as if” equilibrium price from λp_i to U_i , the hypothetical price that would have to be paid to clear the “as if” competitive market.

In the simplified world of this model, it is easy to analyze the welfare loss of a distorted price system. As a reference point, I will take the constrained second-best optimal-rationing solution (9) of problem (6)–(8). Such an allocation maximizes utility subject to budget constraint (4) and goods-availability constraint (5). In some sense, the utility difference between it and the shortage equilibrium, to be denoted L , represents the waste of search and storage activity. There is a simple expression linking L with the coefficient of price distortion δ .

THEOREM 2: *The welfare loss of a stationary shortage equilibrium compared with an optimal rationing scheme is*

$$(34) \quad L = \delta \left(\frac{1}{a} + \frac{1}{b} \right)$$

where a is the elasticity of disutility of effort

$$(35) \quad a \equiv \frac{v}{V} e$$

while b is the elasticity of disutility of storage

$$(36) \quad b \equiv \frac{w}{W} s.$$

PROOF:

From (21), the allocation of goods is the same in (18)–(20) as in (6)–(8). Therefore, from (1) the difference in utility attained is

$$(37) \quad L = V(e) + W(s).$$

Making use of definitions (25), (27), (35), and (36), expression (37) can be rewritten as (34).

Note that shortage losses are first-order in the appropriately normalized measure of

economy-wide price distortion. This is because, unlike the standard second-order deadweight loss (from tax theory) of distorted prices in markets that clear, here malformed prices cause real shortage deformations akin to rent-seeking activity.⁹ Furthermore, the social cost of these shortage deformations enters twice; that is, distorted prices here do double damage. First, they create nonproductive search activity at a social cost of δ/a , which has no other function than to allocate the artificially underpriced goods. Second, price distortions result in goods being tied up by buyers at social cost δ/b in socially unnecessary inventories held throughout the system.¹⁰

Somewhat paradoxically, the higher the elasticity of disutility of effort or storage, the less damage is done by a faulty price system. This is because search or storage activities do not play a directly productive role here. Their only purpose is to allocate artificially underpriced goods. Since buyers can only end up consuming on average what is being made available on average, the goods will end up getting distributed the same way no matter what are the $V(e)$ or $W(s)$ functions. When people suffer greater incremental pain from additional search or storage activity, they will actually end up with less total disutility, because they will simply avoid waiting in lines or stocking up their closets. Hence, the paradoxical conclusion is that greater potential pain is less actual pain.

⁹For an analysis of rent-seeking activity, see James Buchanan et al. (1980) and the references cited therein.

¹⁰The reader may wonder why distorted prices do double damage in this model. For concreteness, take the linear case $a = b = 1$. Then, (34) becomes $L = 2\delta$. Yet in a standard model where the waiting-effort cost is proportional to the amount of the good bought, the total loss of consumer surplus would be equal to the price subsidy times the quantity purchased, or δ . Where, then, does the extra term of δ come from? In a standard model, there is no need to hold inventories. In the present square-root inventory model, the marginal cost of carrying inventory is always equal to half the average cost. Since equilibrium essentially requires that the marginal cost of holding inventory be equal to the amount of price subsidy, it follows that the average cost of holding inventory must equal twice the price subsidy. I am indebted to Paul R. Milgrom for providing this intuitive explanation of why $L = 2\delta$ when $a = b = 1$.

There is another seeming paradox here, which makes an important point. In an environment of widespread shortage due to a malfunctioning price system, ordinary notions of "real income" lose their meaning. Actually, if there is sufficient price distortion, higher income can, other things being equal, mean lower welfare. If enough goods are in shortage, more "real income" can translate primarily into longer lines and greater hoarding rather than increased consumption per se.

Other things (including prices) being held equal, when nominal income is raised there are two effects. More money is available to spend on nondeficit goods ($i|U_i = \lambda p_i$), which increases welfare. This is the usual sense in which higher real income is better. However, in a shortage situation there is also a detrimental side, which might be called the "money-overhang effect." As income is raised, the marginal utility of income (λ) declines, which increases the difference between value and price ($U_i - \lambda p_i$) for deficit commodities, which in turn leads to greater search (e_i) and storage (s_i) effort and raises the welfare loss L . This money-overhang effect is more pronounced as the deficit commodities constitute a greater fraction of all goods. In the extreme case, the money-overhang effect can be so severe that more income can actually result in lower welfare.

There is a slightly different way of constructing and interpreting the model that makes the same basic point. Take as given a fixed vector of goods q to be allocated. Consumers end up with the same final allocation of goods $d = q$ no matter what. For a given subset of (deficit) goods, prices are frozen at below market-clearing levels. For the remaining (available) goods, prices move freely to their competitive levels, which just clear the fixed supplies, taking account of consumer income. As money income increases in this setup, the consumers will be made unambiguously worse off. Price distortion on the available goods will always be zero. However, for the deficit commodities, the coefficient of price distortion will increase with income as the marginal utility of income declines. For the same final allocation

of goods, lower fixed prices or higher nominal income decreases consumer welfare.

Thus, standard measures of "real income" may be a quite unreliable indicator of welfare in situations of economic shortage. It is then not difficult to understand the temptation to eliminate search and storage costs by imposing rationing, even though such measures introduce problems of their own.¹¹

In the model as presented, the production or supply side is taken as more or less given. If the supply side were adversely affected by shortages, either because people are so busy finding and keeping goods that they have less time to work or because it is difficult to maintain morale on the job when pay buys so little, the ingredients are present for a vicious circle.¹² An increased money overhang decreases welfare, which then feeds back to lower production, which depresses welfare further. In such a world, income-increasing tendencies that exacerbate a money overhang can be very dangerous indeed.

This point can be illustrated rather simply as follows. Suppose that a unit of labor-time input produces a unit of homogeneous output. Each person is endowed with one fixed unit of labor-time, which can be divided continuously between producing output or engaging in non-directly-productive search and storage activity. The delivery price of the single good (or, in an alternative interpretation, the wage) is fixed by the government at ω , whereas the sales price of the good is fixed by the government at $p < \omega$. Thus, the subsidy of cost over price per unit of the good is $\gamma \equiv \omega - p$. Suppose each person must pay a fixed per capita tax of $\theta > 0$ to the government. Let y be the amount of the good produced per capita. (The remaining time $1 - y$ is spent on search and storage activity.) Then per capita dis-

¹¹ Throughout this paper, black-market activities are ignored. It could be argued that pressure toward black markets might increase with the degree of price distortion.

¹² Indeed, the Soviet economy is showing signs of this vicious circle.

possible income is $\omega y - \theta$, which in equilibrium must equal the value of goods purchased py . Rewriting this latter relation gives $y = \theta/\gamma$. Other things being equal, the greater the price subsidy γ , the greater is the incentive to engage in nonproductive search and storage activity, and the lower is per capita production (and consumption) of actual goods and services. Note too that other things being equal, a higher per capita tax (within the relevant range) actually raises productive output, because it lessens the monetary overhang caused by price subsidization. It should be readily apparent that if this kind of economy gets caught in any kind of spiral between lower standards of living and increased money-wage subsidization, production can implode.

For the sake of a sharp characterization, the analysis has proceeded as if all consumers are identical. A shortage equilibrium will typically exist in the more general case when consumers are different, but it will be more complicated to analyze. Consumers with less income or a lower value of time will end up waiting in line and storing the subsidized products, while people with higher incomes or a greater value of time will tend to seek out the higher-priced goods with shorter lines.¹³

The model of shortage equilibrium presented here presupposes a regular, stationary, well-behaved process. Actually, shortage phenomena frequently display an erratic, nonstationary aspect. To that extent, the analysis presented here probably understates the social loss of price distortions.

IV. Dynamics

The analysis so far has been purely static. A stationary shortage equilibrium is postulated. Everyone expects this steady state to persist forever. Consumer behavior, which is contingent upon this stationary equilib-

rium, reinforces it. As has been shown, the analysis of steady-state shortage equilibrium is eminently tractable. Some suggestive insights emerge about changes in behavior across steady states, but there has been no dynamic analysis as such.

In a model such as this, where inventories are playing a central role, dynamic transitions display an important property not visible from examining steady-state behavior alone. With a change between steady states comes a change in average inventory stocks, which in turn forces a corresponding alteration of consumption flows during the interim. Adjustments toward higher stocks of equilibrium inventories, without a change in supply, must involve an accumulation at the expense of consumption, a kind of "inventory squeeze" of consumption. This in turn leads to an overshooting property in the waiting time of queues, so that short-run welfare temporarily falls below its long-run equilibrium level. The purpose of the present section is to explore this theme in some detail. It turns out that a formal analysis of dynamics for the general case is an extremely formidable task. All that I am able to do here is to provide a suggestive example of the dynamics of one simple case. I believe this example captures well the main elements that are involved in the dynamic properties of an "inventory squeeze." I also believe that the basic features of the example must generalize. However, disequilibrium dynamics is a notoriously difficult area about which rather little is known except that a lot of different things typically can happen. I do not want to claim that all adjustment processes will be as smooth as the example I will describe in detail.

Suppose, then, that the economy starts out in some steady-state shortage equilibrium. This old steady-state equilibrium had been expected to continue indefinitely. Then, suddenly and without warning, some underlying parameters change, which increase the degree of shortage in the economy. To be specific, suppose δ_i increases to δ'_i , but the underlying supply flow of goods does not change. The easiest thing to envisage is an increase of nominal income that exacerbates the degree of monetary over-

¹³ It is even theoretically possible that low-income, low-value-of-time people could be made better off by price subsidies, although this possibility is excluded in a representative consumer world.

hang in the economy. Suppose the new situation is naively expected to last forever.

Using (21)–(23), it is easy to analyze the differences between the two steady states. With $\delta'_i > \delta_i$, the new stationary equilibrium will feature more search effort and larger inventories. Yet this cannot be the entire story of the transition. When the underlying production structure has not changed, consumption will be the same (equal to production) in both steady states, or $d'_i = d_i$. If consumption in the new stationary equilibrium is to be the same as the old, because what has changed is not the underlying production structure but the price of good i relative to income, the economy must go through a wrenching dislocation in making a transition between steady states. There is no way that inventory stocks can be built up from an average per capita level of $s_i/2$ to a higher average per capita level of $s'_i/2$ and have consumption flows remain uninterrupted throughout. With consumption levels the same in beginning and final steady states, but inventory levels higher in the final state, there must be a transition period during which consumption is curtailed to allow stocks to accumulate. In turn, the only allocation mechanism available to force lower consumption is increased waiting time or search costs.

A change from a lower to a higher state of equilibrium shortage involves a change from a lower to a higher level of search time. The greater required effort of the new steady state is bad news enough. The effort level during the transition period is even more awful news because, to induce consumers to curtail consumption and permit inventory stocks to accumulate, effort must “overshoot” its new long-run equilibrium and then only gradually decline to the new steady-state level, which is merely worse than the old.

Suppose the change occurred at time $t = 0$. At time $t < 0$, everyone was expecting the old shortage equilibrium to last forever. Then, at time $t = 0$, δ_i unexpectedly increased to δ'_i . This new condition, too, is expected to be permanent. The typical consumer, when he now goes to wait in line to

make his purchases and restock his inventories at time $t \geq 0$, will attempt to adjust. Projecting the same effort level to obtain the good but at a higher value relative to price, the consumer will initially attempt to buy and to consume more of the good. Since the flow of desired purchases would then exceed the flow of available goods and since price is fixed (by assumption), the length of the queue must increase to throttle back desired purchases to available supply. Even should waiting lines have increased enough to trigger the new steady-state inventory policy, in which desired consumption flow is equal to available supply flow, that is not enough. In the new equilibrium, each consumer wants to hold more inventories and make purchases less often because the ratio of search effort to nominal price is higher than before. That means that every buyer coming to market in the time immediately after $t = 0$ wants to buy more than before in order to stock up to the new inventory level. Then, waiting times must be even higher than the new equilibrium level, to keep potential purchasers away. The effort level to obtain the good in the transition period must be so high that potential buyers are forced to delay purchases by cutting back on consumption and waiting it out until the lines come down to the new equilibrium level.

In Figure 1 are depicted typical “before,” “during,” and “after” patterns of effort, inventory, and consumption. At least this is the pattern of the example I wish to present. Before the shock at $t = 0$, inventory stocks for a representative consumer display the usual sawtooth pattern with periodicity

$$(38) \quad T \equiv \frac{s}{d}.$$

(For notational convenience, the subscript i will henceforth be dropped whenever its use is superfluous from the context.) After adjustment, the new steady-state inventory sawtooth has periodicity

$$(39) \quad T' \equiv \frac{s'}{d}.$$

FIGURE 1. TYPICAL TRAJECTORIES OF EFFORT, CONSUMPTION, AND INVENTORY

I will exhibit one relatively simple dynamic transition path that lasts exactly T' time units. At time $t < 0$, the economy is in the old steady-state equilibrium. During time $0 \leq t \leq T'$, the economy is in a state of transition. For times $t > T'$, the economy is in its new steady-state equilibrium. The transition itself is a dynamic equilibrium because everyone believes it will happen this way, and their subsequent optimizing behavior makes it actually come about. There may be other consistent transition paths, but I believe they must demonstrate the same basic "inventory squeeze" aspect of the path I will describe, only in more complicated form, because average inventory stocks cannot be built up without somehow squeezing consumption flows in the process. I am not bothered by limiting myself to the relatively simple example of a transition described here because: a) it is already complicated enough, b) it illustrates well the basic principles involved, and c) there is little purpose to misplaced generality here when the model itself and the other aspects of dynamic behavior are purposely being simplified as much as possible.

At time 0, it comes as a complete surprise when δ changes to δ' . Suppose that after $t = 0$ everyone believes that the effort required to obtain good i has jumped up discontinuously to level \bar{e} ($> e'$) and is declining linearly back down to level e' during the transition period $[0, T']$, thereafter to remain forever at the new steady-state level e' . This effort profile is depicted in Figure 1.

Also shown is a typical consumer's corresponding inventory stock and consumption flow trajectories.

When the shock hits at $t = 0$, the consumer is unexpectedly caught somewhere in the previously optimal inventory cycle. For all $t < 0$, inventories had been picked up and stored in batches of size s , to be run down at consumption rate d . Suppose at $t = 0$ a consumer has on hand stock σ ($0 \leq \sigma \leq s$). In other words, this consumer made his last purchase at time

$$(40) \quad t_0 = \frac{s}{d} \left(\frac{\sigma}{s} - 1 \right).$$

From $t = 0$ on, the consumer faces the declining effort profile depicted in Figure 1. There is then an incentive to delay the next purchase time by slowing down current consumption, because the further off a purchase can be put into the future, the lower will be the effort cost of the purchase.

In the proposed adjustment, every consumer is induced to lower consumption from rate d to rate

$$(41) \quad d' \equiv d \left(\frac{s}{s'} \right)$$

until stocks run down to zero at time

$$(42) \quad t' \equiv \frac{\sigma}{d'} = \frac{\sigma s'}{ds}.$$

From time t' on to infinity, this typical con-

sumer repeats the new steady-state cycle: inventories of size s' are picked up and stored with periodicity T' [equation (39)], being run down by consuming at rate d .

Thus, the typical consumer with inventory σ at $t = 0$ suffers a decline in consumption by the fraction s/s' over his adjustment period $[0, t']$. By time $t = T'$, all consumers are synchronized in the new steady-state.

To prove that the proposed time profiles $e(t)$, $s(t)$, and $d(t)$ depicted in Figure 1 represent a consistent dynamic transition path, two conditions must be shown to hold. First, the feasibility of these inventory and consumption patterns must be demonstrated. Then it must be proved that each consumer wants to follow this prescribed pattern.

Feasibility means that at any instant the flow of supply is equal to the amount of stock being demanded per unit time. The proposed trajectory is feasible for $t < 0$ and for $t > T'$ because these are, respectively, old and new steady-state policies satisfying (18)–(20). For $t \in [0, T']$, a “spreading out” effect occurs. Buyers arriving to market now are each carrying away larger stocks than before (s' instead of s), but these same buyers are arriving less frequently because they are running down existing stock at a rate of d' , which is lower than d . It turns out that the two effects exactly cancel each other, and in aggregate buyers are taking away the same amount per unit time as in the steady state.

In the old steady state at $t < 0$, a consumer with stock σ at time 0 would have planned on next picking up stock s at time

$$(43) \quad \tau \equiv \frac{\sigma}{d}.$$

After the shock, a consumer with stock σ at time 0 will next pick up stock s' at time t' defined by (42). The ratio of the frequency of buyer arrivals in the old equilibrium to the frequency of buyer arrivals in the transition interval is thus

$$(44) \quad \frac{t'}{\tau} = \frac{s'}{s}.$$

Equation (44) is exactly the ratio of the stock each buyer purchases during the transition interval to the stock each buyer purchases in the old equilibrium. Thus, the total stock demand per unit time is the same, equal to supply, and the proposed trajectory is feasible.

Next it must be shown that, given the effort profile $e(t)$ depicted in Figure 1, each consumer desires to follow the prescribed consumption and stock trajectories $d(t)$ and $s(t)$. For the steady states of $t < 0$ or $t > T'$ this has already been shown by (21)–(23). To show that the effort profile $e(t)$ of Figure 1 induces the depicted pattern of $d(t)$ and $s(t)$ for $t \in [0, T']$, I must make some assumptions about consumption payments and inventory costs in the transition period. I do not think that these assumptions are critical in the sense that they are being made primarily to serve as sufficient conditions for the relatively neat patterns of Figure 1 to emerge. I believe that more general assumptions of a reasonable sort would give the same qualitative features but would be harder to analyze.

In what follows, the consumer's basic decision variable is x , the rate of consumption from $t = 0$ until the inventory stock σ runs out, at which time it is optimal to follow the new steady-state policy. Assume that the money cost of consuming any good is pay-as-you-go. It is proposed that consumption is at rate x for $0 \leq t \leq \sigma/x$ and at rate d for $t > \sigma/x$. The utility cost of following this policy over the interval $[0, T']$ is

$$(45) \quad \lambda p x \left(\frac{\sigma}{x} \right) + \lambda p d \left(T' - \frac{\sigma}{x} \right).$$

Assume further that inventory storage cost is essentially the storage-cost coefficient times the new inventory level times the interval over which it operates. Some stories could be told to support this interpretation, but it is more important to emphasize that virtually any reasonable formulation would yield qualitatively similar results. The inventory-carrying cost of the proposed policy over the interval $[0, T']$ is

then

$$(46) \quad hs' \left(T' - \frac{\sigma}{x} \right).$$

For notational convenience, assume that w and v are normalized to unity.

With $e(t)$ representing effort as a function of time, the total net utility of the proposed policy over the interval $[0, T']$ is then

$$(47) \quad \left(\frac{\sigma}{x} \right) U(x) + \left(T' - \frac{\sigma}{x} \right) U(d) - e \left(\frac{\sigma}{x} \right) \\ - \left[\lambda p x \left(\frac{\sigma}{x} \right) + \lambda p d \left(T' - \frac{\sigma}{x} \right) \right] \\ - hs' \left(T' - \frac{\sigma}{x} \right).$$

The consumer chooses x to maximize (47), yielding the first-order condition

$$(48) \quad \frac{\sigma}{x} U_i(x) - \frac{\sigma}{x^2} U(x) + \frac{\sigma U(d)}{x^2} \\ + e' \left(\frac{\sigma}{x} \right) \frac{\sigma}{x^2} - \frac{\lambda p d \sigma}{x^2} - \frac{hs' \sigma}{x^2} = 0.$$

The expression $e'(\sigma/x)$ stands for the time derivative of the effort function evaluated at $t = \sigma/x$.

For the consumer to be choosing to follow the prescribed path of Figure 1, condition (48) must hold for the value

$$(49) \quad x = d'$$

where d' is defined by (41). Substituting (49) and (41) into (48) and rearranging yields

$$(50) \quad e' \left(\frac{\sigma s'}{ds} \right) = U \left(\frac{ds}{s'} \right) - U(d) \\ - \frac{ds}{s'} U_i \left(\frac{ds}{s'} \right) + \lambda p d + hs'.$$

As the parameter σ varies from 0 to s , condition (50) defines the slope of the required effort function $e'(t)$ on the interval

$[0, T']$. Since the right-hand side of (50) does not contain σ , the slope of the effort function, hereafter denoted e' , must be constant throughout $[0, T']$. In other words, $e(t)$ is a straight line, as depicted in Figure 1.

From applying (32) to (50),

$$(51) \quad e' = 0 \quad \text{for } s' = s.$$

In other words, a transition from an old steady state to a new steady state that is the same as the old steady state is no transition at all.

The concave function

$$(52) \quad U(y) - \lambda p y - \frac{hs'y}{d}$$

has a unique maximum, where its derivative is zero, at $y = d$ defined by the first-order condition (32). In particular, this means that, for $y = ds/s'$,

$$(53) \quad U(d) - \lambda p d - \frac{hs'd}{d} \\ \geq U \left(\frac{ds}{s'} \right) - \lambda p \left(\frac{ds}{s'} \right) - \frac{hs'}{d} \left(\frac{ds}{s'} \right).$$

Substituting (53) into (50) and rearranging yields

$$(54) \quad e' \leq - \frac{ds}{s'} \left[U_i \left(\frac{ds}{s'} \right) - \lambda p - \frac{hs'}{d} \right].$$

From concavity of expression (52), the derivative with respect to y of (52) is greater than zero for $y < d$. Letting $y = ds/s'$, this observation applied to (54) yields

$$(55) \quad e' < 0 \quad \text{for } s' > s.$$

Since e' is continuously differentiable in s' , (51) and (55) imply that, when s' is sufficiently close to s ,

$$(56) \quad e' > 0 \quad \text{for } s' < s.$$

It has been shown, then, that in undergoing a change from an old steady state with a lower degree of price distortion to a new

steady state of higher price distortion, there will occur a transition phase in which effort is greater and consumption is lower than in either steady state. Conversely, during a transition to a state of less price distortion, effort will be lower, and consumption will be higher.

All of this means that increased price distortion has particularly painful immediate effects as goods are squeezed out of consumption and into inventory stocks. The situation may stabilize later of its own accord to a still unsatisfactory level, but the period immediately after an increase in monetary overhang is likely to be one of especially acute shortage symptoms.

The good news is that if price distortion can be lessened then society can go on a temporary binge as unwanted inventories are worked off into extra consumption. Reversing the shortage process—by raising prices or lowering money incomes—results in a “consumption dividend” from unneeded stocks coming out of storage into general circulation.

V. Conclusion

This paper has presented a formal model of consumer behavior under conditions of shortage. A critical role in allocating shortage goods is played by the directly unproductive activities of search and storage. It is possible to express directly these two key variables as simple functions of the underlying degree of price distortion and, therefore, to analyze easily the relation between price distortion, search effort, and goods stockpiling. “Hoarding psychology,” or what might better be called “defensive hoarding,” can be thoroughly analyzed as an economic phenomenon by extensions of standard economic theory. In shortage equilibrium, everyone must expend effort to locate and hoard goods because everyone else is expending effort to locate and hoard goods.

A clear theme of the paper is that price distortion and monetary overhang can present very severe threats to the normal functioning of an economy. The essential inadequacy is in the monetary domain of prices and income, not in the real economy of production and distribution. The seeming paradox of the missing Soviet soap must be resolved not by scapegoating distributors or by making token increases in soap production, which do little to alleviate the underlying problem. Instead, prices on soap must be increased, or incomes lowered, so that consumers can move toward a better state where they are not impelled to hoard large inventories. The essential issue is to remove the incentives that lead to excessive inventory stocks blocking what should be a direct flow of goods from production to consumption.

A Natural Experiment in the Organization of Entry-Level Labor Markets: Regional Markets for New Physicians and Surgeons in the United Kingdom

By ALVIN E. ROTH*

The histories of seven regional markets for new physicians and surgeons in the United Kingdom are considered. Like the American market, these markets have experienced failures that led to the adoption of centralized market mechanisms. Because different regions employ different centralized mechanisms, these markets provide a test of the hypothesis that the success of the American market is related to the fact that it produces matches which are stable in the sense that no two agents mutually prefer to be matched to one another than to their assigned partners. Even in the more complex U.K. markets, this kind of stability plays an important role. Centralized markets that produced unstable matches in environments in which agents could act upon instabilities fared no better than the decentralized markets they replaced. (JEL C78, D00, J41, J44)

In this paper, I seek to analyze a unique natural experiment that has emerged over the last 20 years in the United Kingdom, concerning the organization of entry-level labor markets. The markets in question are those in which newly graduated medical students seek their first hospital positions, called preregistration house-officer positions. These positions are closely comparable to first-year intern positions in American hospitals (although there are some important differences, which will be

discussed). The natural experiment arises because these markets are organized differently in different regions of the National Health Service. These different markets allow investigation of how market behavior is influenced by market organization. This diverse set of markets also invites comparison with the American market for interns and allows the hypothesis advanced in Roth (1984a) about the behavior of that market to be tested and refined.¹

The particular forms of market organization in the United Kingdom that are the subject of this paper arose in reaction to problems that emerged in the 1960's. Prior to the mid-1960's, the preregistration house-officer markets in the various regions of the National Health Service were largely run in a decentralized way, with students responsible for finding positions on their own and with consultants (as senior physicians and surgeons are called) responsible for filling the positions under their supervision. Competition among students for desirable positions and among consultants for desirable house officers eventually led to

*Department of Economics, University of Pittsburgh, Pittsburgh, PA 15260. In the course of gathering information about the markets described here, I have been helped by numerous British physicians and medical administrators, who have taken the time to correspond with me at length on these matters and sometimes to unearth old records. Among those who have taken pains to help me, I would be remiss not to mention Drs. J. Anderson, T. J. Bayley, P. G. Bevan, K. C. Calman, S. C. Farrow, J. Fraser, F. J. Goodwin, T. M. Hayes, K. Johns, J. H. Lazarus, D. McInnes, G. A. Moge, R. Mulligan, K. M. Parry, R. P. Ryan, D. A. Shaw, D. M. Taylor, H. R. A. Townsend, and N. D. Wright. Of course, they are in no way responsible for any errors or omissions in my account of these markets, nor for the conclusions reached in this paper. I am also grateful to Dr. Susan Mongell, who helped assemble the published literature on this topic. This work has been supported by the National Science Foundation and the Alfred P. Sloan Foundation.

¹Some of my conclusions about this comparison were earlier described briefly in Roth (1990).

these positions being filled earlier and earlier in the students' education. The situation is described as follows by A. Doig and G. Munday (1969):

The filling of preregistration house-officer posts by private arrangements between consultants and students is considered unsatisfactory by most students and by an increasing number of consultants. This practice allows consultants to offer appointments to promising students early in their clinical years and often causes subsequent regret on the part of those who accept when they are later offered more desirable posts; broken agreements cause considerable inconvenience and irritation to consultants. [p. 1250]

J. Alexander-Williams and Ivor Stephenson (1973), writing about the situation in Birmingham prior to the mid-1960's, describe things similarly.

Our graduates who wished to take posts in the teaching hospital insisted on promises earlier and earlier in their undergraduate careers as a result of the many more attractive posts in the region being promised years in advance to graduates imported from other regions. [p. 605]

Doig and Munday further note that

...an initial attempt was made to effect improvement by simply standardising the dates for the receipt of applications and the offering of posts; this procedure had the unfortunate effect of telescoping many of the difficulties and frustrations which had previously occurred over a year or more into a much shorter period. [1969 p. 1250]

This early history is strikingly similar to that of the American market for interns from 1900 to 1951, described in Roth (1984a). By 1944, the standard date at which internship appointments were made in the American market had advanced to two full years before the internship was to begin. In 1945, standardized appointment dates nearer the beginning of employment were

successfully established through the intervention of the medical schools. However, problems manifested themselves in the waiting period between the time offers of internships were made and the time students were required to accept them. Roth (1984a) describes these as follows:

...a student who, was offered an internship at, say, his third choice hospital, and who was informed he was an alternate (i.e., on a waiting list) at his second choice, would be inclined to wait as long as possible before accepting the position he had been offered, in the hope of eventually being offered a preferable position. Students who were pressured into accepting offers before their alternate status was resolved were unhappy if they were ultimately offered a preferable position, and hospitals whose candidates waited until the last minute to reject them were unhappy if their preferred alternate candidates had in the meantime already accepted positions. Hospitals were unhappier still when a candidate who had indicated acceptance subsequently failed to fulfill his commitment after receiving a preferable offer. In response to pressure originating chiefly from the hospitals, a series of small procedural adjustments were made in the years 1945-51. [p. 994]

These adjustments primarily involved shortening the time during which students were allowed to hold offers without either accepting or rejecting them. By 1949, a time of only 12 hours had been rejected as too long, and by 1951 it was widely recognized both that there were serious problems in the last stage of the matching process and that these could not be resolved by compressing this last stage into shorter and shorter time periods.

At this juncture, a centralized (and computerized²) matching procedure was proposed and adopted in the American market.

²Initially the procedure was carried out with card-sorting machines.

Students and hospital programs continued to interview one another as before, but then students submitted to a central clearinghouse a list of hospital programs ranked in order of preference, and hospital programs submitted a list of students. On the appointed day, students were notified of the hospital program to which they had been matched, hospital programs were notified of the students with which they had been matched, and both hospitals and students were encouraged to sign the necessary contracts with one another. Note that at every stage of the procedure, from the decision to submit preference lists to the decision whether to accept the match ultimately proposed, this matching procedure was instituted as a *voluntary* procedure. It is therefore particularly notable that it achieved very high rates of voluntary participation, with the proposed matchings accounting for the large preponderance of jobs filled in this market for many years following its inception. This matching procedure has survived for many years; the algorithm used today to accomplish the match is still essentially the one first used in 1952.

When a Royal Commission on Medical Education (1965–68) issued a report on the problems confronting the preregistration market, the organization of the American market presented an obvious alternative. Many medical schools and their affiliated regional hospitals introduced centralized matching procedures, but different regions used different algorithms to determine the match from the submitted preferences. (Some, but by no means all, of these centralized schemes were implemented by computer.) It appears that more than a dozen regional matching procedures were introduced, but in contrast to the American experience, only a few have survived to the present. Most failed to solve the problems that motivated their introduction and were abandoned.

The principal goal of the present paper is to investigate what common properties might distinguish those centralized procedures that failed and were abandoned from those that succeeded and are still in use today. This will also present an opportunity

to test and refine, in a different environment, the hypothesis advanced in Roth (1984a) about the success of the centralized procedure introduced in the American market.

It was shown in Roth (1984a) that the algorithm employed in the American market produces a *stable* matching in terms of the submitted preferences, where a matching is called stable if no student or hospital is matched to an unacceptable mate and if there is no student and hospital not matched to one another who would both prefer to be matched to each other than to (one of) their partner(s) in the matching. The next section recounts briefly how the major developments in the American market can be explained in terms of stability or the lack of it, which leads naturally to the hypothesis that the success of the American procedure is intimately related to the stability of the matching it produces. Therefore, one goal of the present study is to provide a test of this “stability hypothesis” as it applies to the U.K. markets. Another goal is to consider the incentives agents may have to submit other than their true preferences and the effects this may have.

The regional markets in the United Kingdom provide a stringent test of the stability hypothesis for two reasons. First, administrative authority is more centralized in those markets than in the American market. In some of the regions in which a centralized matching procedure was tried in the United Kingdom, for the period in which it was in effect it was the only way to formalize employment agreements. In contrast to the American market, students in such regions could not decline a job with which they had been matched and arrange instead another job in the same region, and consultants could not decline a student with whom they had been matched in favor of another participant in the match.³ However, as will be seen, it was sometimes possible for students and consultants to circumvent the match by

³However, students could sometimes arrange jobs in other regions.

coordinating with one another before the formal match. The second reason why instabilities might have less consequence in the U.K. markets than in the American market is that the U.K. markets are smaller than the American market by a factor of about 100. Consequently, there are many reasons why, even in regions in which other avenues to formalize employment agreements existed in principle, students and consultants might feel obliged to "play by the rules" and accept a suggested match, even if a better one might have been available. Such reasons might not apply in the much larger and more impersonal American market.

Even in the U.K. markets, the stability of matchings plays an important role, as will be seen below. Perhaps even more important than the formal stability conditions is whether agents can anticipate (or detect *ex post*) and act upon any instabilities that may occur. The centralized markets that were unstable in this way fared no better than the decentralized markets they replaced.

This paper concentrates on seven different procedures by which regional markets in the United Kingdom have been organized. These seven are all of those for which I have been able to obtain sufficiently precise descriptions of the matching algorithm (all seven were computerized). Of these seven, two are based upon modifications of an algorithm that always produces stable matchings, and both of these have controlled the unravelling of appointment dates and survived to the present. The five remaining schemes are based upon algorithms that may frequently produce instabilities. Only two of these have survived (and these are in the two smallest markets); the other three have been abandoned.

The organization of this paper is as follows. Section I discusses the American market. Section II describes the chief differences between the American market and the U.K. markets and describes a formal model suitable for the U.K. markets. The main result of this section is that, even at a stable matching, in these markets there may exist higher-order instabilities of a kind not present in the American market. Section III

begins the analysis of particular market organizations in the United Kingdom, starting with three defunct schemes, which all had particularly severe problems due to the fact that agents had incentives to submit other than their true preferences and to form pairwise coalitions prior to the formal match. Section IV discusses the two markets organized around stable matching procedures and the modifications that have been made in each; and Section V considers the two other surviving schemes and the particular markets in which they operate. Section VI considers some of the difficulties presented by the fact that there is no real national market in the United Kingdom for preregistration positions, but only a collection of regional markets, and conclusions are presented in Section VII. Some of the necessary formal apparatus and proofs will be deferred to the Appendix.⁴ (See Roth and Marilda Sotomayor [1990] for a full account of the literature.)

I. The American Market

In the American market, students each seek one position, while each hospital seeks some number of students.⁵ The size of the market has approximately doubled since 1952: today roughly 20,000 positions are offered annually.

Interns' salaries are part of the job description and are not negotiated by each hospital and intern. Therefore, salaries will not play an explicit role in the model but will simply be one of the factors that determine the preferences that students have over hospitals. Similarly, hospitals can rank students. Because a hospital typically employs more than one student, a full description of a hospital's preferences must include how it

⁴Because of the way the paper is organized, it may be easiest to read the Appendix last, rather than referring to it whenever a proof is deferred to the Appendix.

⁵Strictly speaking, the agents on the institution side of the market are hospital programs rather than hospitals, since different internship programs within a hospital are separately administered and students apply to specific programs.

evaluates alternative groups of students. A simple assumption connecting a hospital's preferences for groups of students to its ranking of individual students is that, if two groups of students differ only by a single individual, the hospital prefers the group containing the higher-ranked individual. Preferences of this sort are said to be *responsive* (to the hospital's ranking of individual students). (More general assumptions are possible, as will be discussed in the next section.) A student is *unacceptable* to a hospital if the hospital would prefer to keep a position vacant rather than fill it with that student, and a hospital is unacceptable to a student if, rather than accept one of its positions, the student would prefer to remain unmatched (and seek employment in a secondary market).

An outcome of the market is a matching of students and hospitals, such that no hospital is assigned more students than it has positions and no student is assigned to more than one position. A matching is *stable* if no student is matched to an unacceptable hospital, no hospital is matched to an unacceptable student, and no student and hospital who are not matched to one another would both prefer to be matched together. (Specifically, the hospital must prefer the student to one of the students it is matched with, or if it has some unfilled positions, it must prefer the student to leaving a position unfilled.)

In Roth (1984a), I undertook to explain three episodes in the history of this market. From 1945 through 1951, the market was characterized by chaotic last-minute recontracting, with students seeking to improve on the positions they had been firmly offered (and had sometimes accepted) by contacting the hospitals they preferred and with hospitals sometimes pressuring students into premature decisions in order to be able to contact students on their waiting lists promptly. This behavior persisted despite repeated attempts by various medical organizations to establish more orderly norms of behavior. However, from 1952, following the introduction of the centralized matching procedure, until the mid-1970's, there was a very high degree of voluntary orderly partic-

ipation, with in the neighborhood of 95 percent of American medical school graduates participating in the matching procedure and ultimately being offered and accepting the position they were matched with. However starting in the mid-1970's, as increasing numbers of married couples sought to obtain two positions in the same vicinity, the rate of participation in the match began to drop, with high percentages of married couples seeking and finding positions outside of the centralized match. So there are two transitions to explain: 1) the transition from chaotic recontracting to orderly voluntary participation that took place in 1952 and 2) the transition from uniformly high rates of participation among medical school graduates prior to the 1970's to the defection of married couples in the late 1970's and early 1980's.

The stability hypothesis is based on the demonstration in Roth (1984a) that the 1952 matching algorithm produces a stable matching (in terms of any preferences that may be submitted) and that the procedure used to assign married couples two jobs in the same vicinity was particularly prone to produce unstable matchings.⁶ Note that a student who has been offered or has had proposed to him a specific job (or a couple which has been matched with a pair of jobs) has only to make a few phone calls to determine whether any of his preferred hospitals would be willing to offer him a position, so the problem of determining whether there are any exploitable instabilities is not a difficult one. Thus, the "stability hypothesis" applied to this market is that the chaotic conditions prior to 1952 reflected the instabilities then present in the market, that the success of the centralized procedure was

⁶In recent years, changes in the way married couples are handled by the match show some signs of ameliorating this problem. However, the problem is not completely tractable, since it was shown in Roth (1984a) that, when there are married couples in the market, the set of stable matchings may be empty. It should also be noted that other developments in the match during the 1970's contributed to the decline in participation during that period.

due to the stability of the matching it produced, and that the decline in participation among married couples in the 1970's was because they once again found instabilities.

Of course, even though the stability hypothesis seems to account for the major developments in this market, the real explanations might lie elsewhere. For example, it might be postulated that *any* centralized market organization would have solved the problems experienced prior to 1951 and that the experience of married couples has less to do with instabilities of the kind dealt with here than with the difficulties young couples have in making decisions. Therefore, it is particularly illuminating to be able to consider the kind of natural experiment, involving both stable and unstable centralized matching mechanisms, that one finds in the United Kingdom.

Before moving on to the U.K. markets, it will be useful to make two somewhat technical observations relevant both to those markets and to the American market. The first is that agents may have incentives to submit rank-orderings to the centralized matching procedure that differ from their true preferences.⁷ It was shown in Roth (1982) that no stable matching mechanism exists that makes it a dominant strategy for all agents to state their true preferences, and it was shown in Roth (1985a) that no stable procedure can make it a dominant strategy for all hospital programs with more than one position to rank students in order of their true preferences. In the American market, stating true preferences is not a dominant strategy for either students or hospitals.

This raises another question about the stability hypothesis: if agents may have reason not to submit their true preferences to the centralized matchmaker, then the fact that the matching algorithm produces a matching that is stable with respect to the

submitted preferences does not assure that the matching is stable with respect to the true preferences (i.e., the preferences according to which agents search for and accept alternative opportunities).

One approach to addressing this question is to consider what will happen when the rank-orderings that agents submit are in equilibrium, even though they may be different from the true preferences. It was shown in Roth (1984b) that, when algorithms equivalent to the one used in the American market are employed, every Nash equilibrium in undominated strategies yields a matching that is stable with respect to the true preferences (as well as to the stated preferences) in the special case arising when all hospital programs have only a single position to fill. In the (actual) case, when hospitals fill multiple positions, fewer strategies are dominated, and so only weaker results have so far been obtained: there are equilibria at which the resulting matching is stable with respect to the true preferences, and other equilibria such that it is not (Roth, 1985a). Another approach is to ask whether the agents in the market have the kind of information about one another's preferences needed to profit from submitting rank-orderings different from their true preferences. (These information requirements are considerable; cf. Roth, 1989.) If not, submitted preferences might approximate true preferences sufficiently to produce stable outcomes. Viewed in this way, the question remains largely an empirical one, which gives further reason to make additional observations of the kind considered in this paper.

The second technical observation concerns the significance of defining stability in terms of individual agents and pairs of agents, without reference to larger coalitions of agents, such as coalitions consisting of a hospital and several students (all of whom might be employable by the same hospital) or coalitions consisting of multiple hospitals and students. When the rules of the market are that any student and hospital may sign a contract with one another if they both agree, the following result from Roth (1985b) says essentially that nothing is

⁷In 1951, an algorithm for the American market was proposed that gave agents clear incentives to state rank-orderings different from their true preferences. For this reason, it was replaced by the 1952 algorithm, which was claimed to give agents no such incentives.

lost by not considering such coalitions explicitly.

PROPOSITION 1: *The set of stable outcomes equals the core defined by weak domination⁸ of the market in which hospitals employ multiple students but students take only one position.*

It will be seen that the conclusions of Proposition 1 do not carry over to the U.K. markets considered next, as a consequence of the fact that most students seek two positions in those markets.

II. The U.K. Markets

A medical school graduate in the United Kingdom is eligible only for provisional registration with the General Medical Council. To become eligible for full registration, a doctor must complete 12 months in a pre-registration position, typically six months in a medical position and six months in a surgical position. These positions are supervised by different consultants and are arranged separately, so each graduating medical student must typically find two pre-registration positions. An outcome of this market is thus a matching of students and consultants such that no consultant is assigned more students than he has positions and no student is assigned more than *two* positions, one medical and one surgical.

Most positions are filled on a regional basis, with graduates of a given medical school going to one of the associated teaching hospitals or to other hospitals in the

same region.⁹ Despite their regional character, these markets have a centralized component absent from the American market; the Department of Health and Social Security sets targets for the number of preregistration house-officer posts for each English Regional Health Authority. These regional markets are two full orders of magnitude smaller than the American market: for 1983 the largest English region was the West Midlands, with just over 300 positions, and the smallest was East Anglia, with just over 100 positions.

The fact that students seek two positions, rather than one as in the American market, means that a different model must be used to represent the market. The simplest modification is to assume that students have separate rank-orderings over medical consultants and over surgical consultants. As in the model of the American market, consultants have rank-orderings over students, but now *both* sides of the market must have preferences not just over individuals but over sets; that is, consultants have preferences over groups of students, and students have preferences over pairs of jobs. Again, the simplest assumption is that these preferences are responsive to the rank-orderings of individuals, as defined in the previous section. As before, a matching is stable if no matches are unacceptable and if no student and consultant who are not matched to one another would both prefer to be matched together. However, even when the assumptions of the model are kept closely comparable to those for the American market in this way, the fact that matchings are many-to-two (i.e., consultants have more than one student, and students need two jobs) rather than many-to-one has the consequence that stable matchings need no longer be in the core of the market or even be Pareto efficient. That is, in this market there is no

⁸An outcome x of a market is *dominated* if there is some coalition S of agents that, by trading among themselves, can obtain allocations they all prefer to x . The outcome x is *weakly dominated* if such a coalition S can obtain allocations that all its members like at least as well as x and that at least one member strictly prefers to x . The core is the set of outcomes that are undominated, and the core defined by weak domination is the subset of the core consisting of outcomes that are not even weakly dominated. Any core outcome is Pareto optimal.

⁹However, in London, where there are many more graduates of local medical schools than local preregistration positions, medical schools commonly have arrangements with hospitals elsewhere.

parallel to Proposition 1. Instead, one has the following result, whose proof is in the Appendix:

PROPOSITION 2: *In the many-to-two matching model with responsive preferences, the set of stable matchings is nonempty for all preferences, but a stable matching need not be in the core and need not even be Pareto optimal.*

The proposition implies that, even when no student and consultant can together arrange to do better than a given matching, there might be a larger coalition, consisting of many consultants and students, who by rearranging job assignments could obtain preferred assignments for all its members. Needless to say, identifying and organizing large coalitions may be more difficult than making private arrangements between two parties, and it will become clear in what follows that the set of stable matchings is still of primary concern.

There are still further generalizations that must be made to the model to allow it to represent faithfully the variety of special constraints found in the various regional markets. In particular, the assumption that agents have responsive preferences must sometimes be relaxed to allow more complex connections between rank-orderings of individuals and preferences over groups.

On the student side of the market, these complexities arise because students require one of each of two types of jobs. However, perhaps the most unusual example of the sort of complicated preferences I have in mind arises on the consultant side of the market administered from Edinburgh. Following what I gather must have been traditional practice¹⁰ before the introduction of a centralized matching scheme, surgeons have the option of indicating that they do not wish to employ more than one female preregistration house officer at a time. Therefore, a consultant surgeon could conceivably submit a rank-order list in which his top four choices, say, were female, but

nevertheless indicate that he wishes to employ at most one of these at any one time.

It is easy to see that these preferences are not responsive to the rank-ordering of individuals as discussed above, since the surgeon in question would prefer to employ his first and fifth choices rather than his first and second choices. Similarly, students clearly prefer one medical and one surgical position to any other combination, regardless of their preferences for individual positions. It will therefore sometimes be convenient to model agents' preferences for sets of alternatives directly, without explicitly considering their rank-orderings of individual students or positions.

Thus, faced with a set S of student applicants, a consultant C can determine which subset of S he would most prefer to hire. We call this C 's choice from S , and denote it by $Ch_C(S)$. That is, for any set S of students, C 's choice set is $Ch_C(S) = S'$ such that S' is contained in S and S' is (at least weakly) preferred to any other subset S'' of S . It will be convenient (but not essential) in what follows to assume that all agents have strict preferences, so that the choice set is unique. Thus, a consultant's preferences are given by a rank-ordering of sets of students, $S_1, S_2, \dots, S_k, \Phi, \dots$, with S_1 being his first-choice set of house officers and so forth (and with any unacceptable set being less preferred than the empty set). These preferences determine the choice function (i.e., for any set S , $Ch_C(S)$ is C 's most preferred subset S' of S). A student's preferences over (pairs of) positions can be represented analogously.¹¹ The constraints mentioned above are consistent with the preferences meeting the following condition:

Definition: An agent A (a consultant or a student) has *substitutable preferences* over sets of alternatives (i.e., sets of students or pairs of jobs) if, for any set T that contains

¹⁰Particularly among urological surgeons.

¹¹In this representation of preferences, the requirement that students have one medical and one surgical position would be represented by having sets consisting of a pair of two medical jobs, for instance, be unacceptable to the student.

distinct elements t and t' , if t is in $\text{Ch}_A(T)$ then t is in $\text{Ch}_A(T - t')$.

If a consultant, for example, has substitutable preferences, then if his preferred set of employees from T includes student t , so will his preferred set of employees from any subset of T that still includes t . (This follows by repeated application of the definition.) Therefore, the consultant regards student t and the other students more as substitutes than as complements and continues to want to employ t even if some of the other students in his choice set become unavailable. Note that responsive preferences are substitutable, so this condition on preferences is a generalization of what has been considered so far.¹² One can similarly generalize the definition of stability as follows.

Consider a matching μ which assigns to each consultant C the set of students $\mu(C)$ and to each student s the set of (no more than two) jobs $\mu(s)$. The matching μ is stable if there is no student s who would prefer to reject one of the jobs in $\mu(s)$, no consultant C who would prefer to reject one of the students in $\mu(C)$, and no student s and consultant C who are not matched to one another but who would prefer to be. That is, μ is stable if there is no student s such that $\mu(s) \neq \text{Ch}_s(\mu(s))$, no consultant C such that $\mu(C) \neq \text{Ch}_C(\mu(C))$, and no student s and consultant C such that s is not in $\mu(C)$ [and so C is not in $\mu(s)$] but such that s is contained in $\text{Ch}_C(\mu(C) \cup s)$ and C is contained in $\text{Ch}_s(\mu(s) \cup C)$. It is possible to state the following proposition, which is proved in the Appendix:

PROPOSITION 3: *In many-to-two matching, when all agents have substitutable preferences, the set of stable matchings is nonempty.*

¹²Substitutable preferences in two-sided matching were first studied by Alexander Kelso and Vincent Crawford (1982). Charles Blair (1988) showed that, in many-to-many matching with substitutable preferences, the core could be empty even though the set of stable matchings is not. (Proposition 2 shows that this is related to many-to-many matching, not merely to complex preferences.)

In summary, although there are clear similarities between the American market for interns and the regional markets in the United Kingdom for preregistration house officers, there are also some important differences. Some of these have to do with the fact that the U.K. regional markets are both more centralized and much smaller than the American market. Other differences have to do with the fact that students in the U.K. markets seek two jobs. As a result of the latter differences, preferences in the U.K. markets cannot always be modeled as simply as in the American market and require the more general model described in this section.

In considering the operation of the various regional markets, the more general model will be required to establish what is a stable matching. However, when the procedures that produce unstable matchings are considered, it will be possible to demonstrate the instabilities even within the confines of the simpler models.

III. Matching by Priority: Newcastle, Birmingham, and Edinburgh (1967)

This section considers three closely related matching schemes, all developed in the late 1960's, and all subsequently abandoned.¹³ In each of these schemes, a student's ranking of a particular consultant was combined with the consultant's ranking of that student to produce a "priority" for that student to be employed by that consultant. The three schemes differ in the way in which this priority was determined, and each will be discussed below with examples. In each scheme, the overall matching of students with consultants was determined by making the individual matches of students with consultants in order of priority. That is, the first step of each of the three algorithms was to make all of the first-priority matches. Then consultants with unfilled positions and students still needing jobs were scanned to

¹³The Edinburgh scheme was replaced around 1969 by another centralized system, considered in the next section.

identify any second-priority matches, and so on.

The schemes introduced in Newcastle in 1967 (A. G. Leishman and R. P. Ryan, 1970) and in Birmingham in 1966 (Alexander-Williams and Stephenson, 1973) were almost identical. They each used the product of the student's ranking of the consultant and the consultant's ranking of the student as the basis for the priorities. If a consultant and student each ranked one another first [a "(1,1) match"], they had a priority of 1. If the consultant ranked the student first but the student ranked the consultant second [a "(1,2) match"], they had a priority of 2, as did a consultant who ranked a student second but was ranked first by the student [a "(2,1) match"]. The two schemes differed in how they broke ties: in Birmingham, ties were broken in the consultant's favor, so that a (1,2) match would have a higher priority than a (2,1) match. In Newcastle, ties were broken in the student's favor.¹⁴

In the scheme introduced in Edinburgh in 1967, priorities were lexicographic in consultants' preferences. That is, (1,1) matches were the first priority, followed by (1,2), (1,3), (1,4), and so forth. Only when all consultants' first choices had been exhausted were other matches [(2,1), (2,2), (2,3), etc.] considered. The following example will illustrate the similarities and differences among these three schemes and also prove the following proposition about them:

PROPOSITION 4: *Each of these schemes may produce unstable matchings.*¹⁵

Example 1. For simplicity, consider six consultants, each of whom has only one position to fill, and six students, each of whom

needs only one position. (It will be clear that the example does not depend on this simplification.) The rank-orderings of the agents are as follows.

$C_1: s_1, \dots$	$s_1: C_1, \dots$
$C_2: s_1, s_3, s_2, s_4, s_5, s_6$	$s_2: C_2, C_1, C_3, C_4, C_5, C_6$
$C_3: s_3, s_4, \dots$	$s_3: C_4, C_3, \dots$
$C_4: s_4, s_3, \dots$	$s_4: C_3, C_4, \dots$
$C_5: s_1, s_2, s_5, s_3, s_4, s_6$	$s_5: C_1, C_2, C_5, C_3, C_4, C_6$
$C_6: s_2, s_5, \dots$	$s_6: C_5, C_2, \dots$

Then the Birmingham algorithm makes the following matches (the priority is indicated in parentheses after each set of matches): C_1s_1 (1,1), C_3s_3 and C_4s_4 (1,2), C_2s_2 (3,1), C_5s_6 (6,1), C_6s_5 (2,6). This outcome is unstable because C_5 and s_5 are one another's third choices, but in the Birmingham match they are not matched to each other, but are each matched to their sixth choices.

The Newcastle algorithm makes the matches: C_1s_1 (1,1), C_3s_4 and C_4s_3 (2,1), C_2s_2 (3,1), C_5s_6 (6,1), C_6s_5 (2,6). This outcome is also unstable with respect to C_5 and s_5 .

The Edinburgh (1967) algorithm makes the following matches: C_1s_1 (1,1), C_3s_3 and C_4s_4 (1,2), C_6s_2 (1,6), C_5s_5 (3,3), C_2s_6 (6,2). This outcome is also unstable, but with respect to C_2 and s_2 , who would each prefer one another to their assigned partners (they are each matched to their sixth choices).

So far, the example has been analyzed as if the agents all state their true preferences. Before considering the incentives that agents may have to do otherwise, it will be illuminating to examine the history of these matching systems after their introduction and how they failed and were abandoned.

The various accounts I have received of the demise of these systems all agree on the main events.¹⁶ The following description is

¹⁴At least initially. A later modification was to reverse this method of tie-breaking. I am indebted to Dr. D. A. Shaw, the Dean of Medicine at Newcastle, for this observation (pers. comm., 13 May 1987).

¹⁵A stronger result, namely that *any* priority matching scheme will sometimes produce unstable matchings, is proved in Proposition 10 in the Appendix.

¹⁶I have been able to obtain the least information about the demise of the Edinburgh system, which by 1969 had already been replaced. I have been able to obtain much more detailed accounts, from multiple sources, of the experiences at Newcastle and Birmingham.

from a letter by Dr. John Anderson, the Postgraduate Dean at Newcastle (pers. comm., 6 May 1987):

To understand why our computerized scheme was discarded [in 1981], you should know that in the Northern Region there are 202 recognised posts (this target is set by the DHSS [Department of Health and Social Security]) in 26 approved hospitals. Each year we normally graduate a maximum of 130 students, so that we regularly have a shortfall of at least 70 and usually more, since a number of our graduates obtain pre-registration posts in other regions. We are therefore a major importing region and each six months fill between 50 and 60 posts with graduates of other regions. However, we have never filled more than 185 posts and this means that up to 20 pre-registration posts are regularly unfilled. Sometimes Senior House Officers will be appointed to these posts, but every six months there is a small number of posts that are left unfilled.

This is the background to our problems, and this imbalance between local graduates and posts explains why the computerized scheme failed. Understandably, consultants in the periphery of the region were anxious to fill their posts as quickly as possible and often entered into private arrangements with undergraduates. ...the practice of making private arrangements outwith the computer match scheme gradually spread to the Teaching Hospitals. Those who stuck rigidly to the scheme often found that they were left without any housemen to appoint, as there was no way of preventing these private arrangements and no sanctions could be introduced against those who operated outside the scheme.

In the late 70s and early 80s an increasing number of problems cropped up, mainly concerning conflicts between private arrangements and the formal application procedure. There was a feeling that the computer scheme was an impersonal mechanism which inhibited personal contact between students and consultants and

shortly before the scheme was discarded we found that in up to 80% of cases students and consultants only used the computer to indicate a first preference.... The main reason for the abandonment of the scheme, therefore, was that there were problems in getting students and consultants to participate in an orderly way, and this led to those who rigidly observed the requirements of the scheme to be penalized.

The experience in Birmingham was similar, but there the centralized procedure, which was initiated in 1966 for a limited group of hospitals, failed after a few years, was resumed on a larger scale in 1971, failed once more, was restarted again around 1978, and was finally abandoned again around 1981. Of the initial experience, Alexander-Williams and Stephenson (1973) say:

Perhaps the most important cause of failure was the lack of enthusiasm by the consultant staff who did not wish to be deprived of the right to choose their junior staff and so, suspicious that the matching programme might allocate them someone whom they did not want, still tended to make a promise to the first acceptable student who approached them. While there are obviously no objections to first choices being mutually agreed, it soon became known among the undergraduates that certain posts were already promised and so began once again the unseemly struggle that the matching programme was designed to avoid. The breakdown of the scheme was to the disadvantage of the diffident student or the one who waited until he had 'surveyed the field.' [p. 606]

Dr. P. G. Bevan, the director of the board of graduate clinical studies at the University of Birmingham Medical School, writes as follows about the most recent attempt (pers. comm., 2 November 1984):

The main cause of failure for this Matching Plan was the fact that too many Consultants did not abide by the conditions and promised their job to

one particular Student.... In view of this we finally abandoned the Matching Plan three years ago.

A recurrent theme in these accounts is that, after the centralized matching had been in use for a short while, increasing numbers of jobs began once again to be privately arranged in advance between consultants and students and that this worked to the detriment of those who tried to participate in the scheme without prior arrangement.

To understand this phenomenon, consider now the incentives which these priority procedures give to the agents. For this purpose, consider again Example 1. (In the example, there are equal numbers of students and positions, but it will be clear that the behavior described below could exist at least as easily when there is an imbalance between the two.) To make the example clear, suppose consultants C_1 – C_4 are in the most desirable teaching hospital, C_5 is in the next most desirable regional hospital, and C_6 is in a relatively undesirable rural hospital. Similarly, suppose students s_1 – s_5 are all top graduates of their medical school, while s_6 has a less distinguished record.

Then, under the Birmingham or Newcastle system, C_5 is gravely disappointed to learn that his new junior house officer will be s_6 , all the more when he learns that student s_5 , whom he liked reasonably well, is quite unhappy with his own appointment and would have preferred to work for C_5 . If C_5 had submitted a rank-ordering on which s_5 was his first choice, they would have been matched, as would also have been the case if s_5 had submitted a rank-ordering on which C_5 was his first choice. The example shows there may be incentives for both students and consultants to submit rank-orderings different from their true preferences.

Furthermore, these priority-ranking systems allow such incentives to build upon one another, so that as more agents adapt their submitted rank-orderings to improve their matches, the greater is the incentive for other agents to do so. To see this, suppose C_5 in Example 1 resolves not to suffer the same fate the following year. He there-

fore approaches one of the good students in the next year's class, in advance of the formal match, and suggests that they mutually agree to be matched, which they will accomplish by ranking one another first in the formal match.¹⁷ The student, chastened by the experience of s_5 the previous year, is receptive. Now consider the situation in the formal match, when a number of positions have been prearranged to be (1,1) matches. Suppose students t_1 , t_2 , and t_3 have made such arrangements with consultants C_3 , C_4 , and C_5 , but consultant C_2 , not knowing this, submits his true rank-ordering, which is $t_1, t_2, t_3, t_4, t_5, \dots$, and t_4 submits his true rank-ordering $C_3, C_4, C_5, C_2, \dots$. Although C_2 does not know it, t_4 is his highest-ranking student who is actually available, and C_2 is t_4 's most-preferred available consultant. However, since the product of their rankings is 16, C_2 could well end up with his 15th-choice student. So when some matches have been prearranged, those not in the know, students as well as consultants, stand to do very poorly if they do not also prearrange their matches. Furthermore, when an agent's top n choices have all arranged to indicate only a first preference in the formal match (as in the above quote from Anderson), then the agent can do no better in the match than to reach such an agreement himself with his $n+1$ st choice. Therefore, the following proposition, which applies as well to the Edinburgh (1967) system,¹⁸ has been proved:

PROPOSITION 5: *It is not a dominant strategy for any agent to submit his true preferences in these priority matching systems.*

¹⁷In the context of these relatively small markets, both parties to such an agreement can be confident that it will be carried out; since a consultant with a reputation for not delivering on his promises will soon find it difficult to attract good junior house officers, and a junior physician is reluctant to incur the enmity of a senior physician in the region in which he hopes to practice.

¹⁸Under the Edinburgh (1967) system, C_2 in Example 1 could have improved his match by ranking s_2 first, and s_2 could have improved his match by ranking C_6 as unacceptable.

Furthermore, there are multiple equilibria at which all agents submit only a first choice.

In fact, Proposition 5 does not capture the full strength of what has been proved. Under priority matching, a student and consultant who rank one another first will be matched regardless of what the other agents do. So the problems of coordination that afflict many equilibria do not arise here: pairs of agents may secure their part of the equilibrium by private arrangement. These results thus go a long way toward explaining both why a high percentage of appointments were soon arranged in advance under these systems and why this worked to the disadvantage of those who tried to arrange employment through these priority-based formal match procedures.¹⁹

IV. Stable Matching: Edinburgh (1969) and Cardiff

This section considers two very closely related systems, both built around the same stable matching algorithm. That the two systems are closely related is not an accident: the Cardiff system was adapted around 1971 from the system initiated in Edinburgh around 1969 to replace the Edinburgh (1967) priority matching system. However the two markets are rather different, with Cardiff regularly having more positions than local graduates and with Edinburgh regularly having more graduates than positions.²⁰ Both systems remain in operation today,

having achieved and maintained high rates of orderly participation.

It is also not an accident that the basic algorithm produces stable matchings, but it is a curious bit of intellectual history. In the 1960's and 1970's the architects of the various matching systems in the United Kingdom knew of the experience of the American markets since 1952, but it was not then known that the American algorithm produced a stable matching. However, unconnected with any of these markets, David Gale and Lloyd Shapley (1962) formulated a simple model of one-to-one matching and defined the set of stable matchings, which in that model equals the core of the game. They also developed a "deferred-acceptance" algorithm (described below) for producing stable matchings and observed that it could be applied as well to problems of many-to-one matching.²¹ Two British computer scientists, D. G. McVitie and L. B. Wilson further explored this algorithm, and apparently through their work, the algorithm came to the attention of Dr. H. R. A. Townsend, the author of the Edinburgh (1969) matching procedure, known as PRAMS (for Pre-Registration Appointment Matching Scheme).²² He used Gale and Shapley's deferred-acceptance algorithm as the basis for PRAMS, adapting it to the requirements of the preregistration market and to the local conditions in Edinburgh. The Edinburgh PRAMS algorithm was subsequently adopted in Cardiff, where it was

¹⁹It appears that something very similar (if not identical) to a priority matching scheme was tried and subsequently abandoned at Sheffield, but I have not included that system among those formally analyzed here because the match was done by a committee, whose exact procedures therefore cannot be determined. However, A. D. Clayden and James Parkhouse (1971 p. 9) report a computer program designed in their words "to mimic the manual allocation," and that program implements a priority algorithm like the Edinburgh (1967) system, except in giving lexicographic priority to students' preferences rather than to consultants' preferences.

²⁰The Edinburgh system is furthermore open to students from medical schools in other regions (Sir James Fraser, pers. comm., 7 May 1987).

²¹Gale and Shapley (1962) concentrated primarily on the one-to-one matching problem, and for many years thereafter one-to-one and many-to-one matching came to be regarded as essentially equivalent. That they are not, in ways that are important for the subject at hand, was first observed in Roth (1985a).

²²Townsend (1981) cites McVitie and Wilson (1971) in the PRAMS.80 manual, which documents the current (as of 1984) version of his computer program, and which he graciously sent to me (pers. comm., 23 November 1984; see also McVitie and Wilson, 1970a, b). Townsend himself is a clinical neurophysiologist, who at the time also held a part-time appointment in Edinburgh's department of Machine Intelligence and Perception, and it was in that capacity that he undertook the design of the PRAMS system (pers. comm., 27 July 1989).

further adapted to local conditions. Before discussing the adaptations introduced in Edinburgh and Cardiff, I will consider first the unmodified²³ deferred-acceptance algorithm for many-to-one matching.

Step 1: Each consultant C with q_C positions makes offers to his q_C highest-ranked acceptable students (or to all of them if there are fewer than q_C).

...

Step k : (i) Each student s rejects all but the highest-ranked of the acceptable offers he has received in steps 1 through $k-1$. (ii) Each consultant C who has received $r \geq 1$ rejections in part (i) of step k , and who now has $q_C - r$ (nonrejected) offers outstanding, makes offers to his $q_C - r$ highest-ranked acceptable students among those who have not yet rejected him. (iii) The algorithm stops at any step $k = T$ at which no rejections are issued, and the resulting matching places each student with the consultant (if any) whose offer he has not rejected and leaves unmatched any student not holding an offer.

Since each student holds at most one unrejected offer at any step of the algorithm and since no consultant makes an offer twice to the same student, the algorithm stops and produces a matching. This matching is stable, because if some consultant C would prefer a different group of students than he receives, then if he has responsive preferences²⁴ he will have proposed to those stu-

dents at an earlier step of the algorithm and been rejected. This implies that these students prefer the positions they get from the algorithm to C , so the matching is stable.

Note that there is another version of the algorithm in which students make applications for positions and each consultant refuses all but the best q_C acceptable offers from among those he has received. While the Edinburgh matching scheme adapts the consultant-proposing version of the algorithm, the present Cardiff version adapts the student-proposing version.²⁵ Both versions produce stable matchings in many-to-one markets.

The markets to which this algorithm was adapted involve many-to-two matchings, and as has already been seen from Proposition 2, this changes the market in important ways. Furthermore, some of the adaptations in both Edinburgh and Cardiff imply that the preferences of the agents are not responsive. Consider the following constraints:

- 1) Each student desires no more than one medical and one surgical position.
- 2) Edinburgh surgeons may specify that they will employ no more than one female house officer in any six-month period.
- 3) In Cardiff (for some of the period under consideration, but not presently), at most one of a student's two positions could be a teaching-hospital position.²⁶

²³Except to allow that some students and consultants may find some matches unacceptable.

²⁴Responsive preferences, which play an essential role in the argument for the case of many-to-one matching, were introduced in Roth (1985a). Earlier treatments of many-to-one matching had argued from analogy with the case of one-to-one matching and had not considered that C 's preferences must be based on comparisons of groups of students. A notable exception is the paper of Kelso and Crawford (1982), which considers preferences defined directly over groups, without reference to an underlying preference over individuals.

²⁵Over the years, the computer code used in Cardiff has undergone a number of programming and procedural changes designed to cope with increasing numbers of positions and with changes in available computers. The current system goes under the name of PASHA (Preferential Allocation System for House Appointments), and during 1973–1982 it went under the name of CHAMP (Computerized House Appointments Matching Plan), during which time the consultant-proposing version of the algorithm was implemented. I am indebted to Dr. Kelvin Johns for documentation of the various systems (pers. comm., 6 November 1984 and 23 June 1989).

²⁶These descriptions abstract somewhat from the actual adaptations. In Edinburgh, a surgeon may actually only specify that he does not wish to employ more than two female house officers, since his positions for two consecutive six-month periods are allocated simul-

Constraints 1 and 2 obviously concern agents' preferences (i.e., certain sets are unacceptable), and constraint 3 can be modeled as part of students' preferences, since it has the effect that students will not (because they cannot) choose two teaching-hospital positions, either during the formal match or in any postmatch exploration of potential instabilities. The Edinburgh adaptation of the algorithm to constraints 1 and 2 is straightforward: students may hold up to two offers at any step in the algorithm but no more than one medical and one surgical, and they must reject the rest. In the Cardiff adaptation to constraints 1 and 3, students could apply at any step of the algorithm to no more than one medical or surgical position and to no more than one teaching-hospital position.²⁷ Subject to these constraints, students' and consultants' offers and rejections within the algorithms are otherwise governed by their submitted rank-orderings of individual positions, as in the deferred-acceptance algorithm described above. (In Edinburgh, students submit two preference lists, one for surgical positions and one for medical. In Cardiff, they submit one preference list containing both kinds of positions.²⁸

taneously. It then remains to schedule the house officers so that two female house officers are not assigned to the same six-month period. Scheduling may present other difficulties as well, some of which may involve "higher-order" instabilities, which will be briefly discussed later. In Cardiff, when constraint 3 was in effect, if some teaching-hospital positions were left unfilled by the initial run of the algorithm, these positions were then "unmarked," so that a student who already had one teaching-hospital position became eligible to fill them.

²⁷This might involve, for example, a student applying at the first step of the algorithm to his first-choice medical position in the teaching hospital and to his fifth-choice surgical position. If he were subsequently rejected by the medical position, he might wish to apply to a surgical position in the teaching hospital, which might be his second-choice position. The algorithm gave him the opportunity to do so, which involved withdrawing his application from his fifth-choice surgical position. Thus, unlike the original deferred-acceptance procedure, applications could be withdrawn as well as rejected.

²⁸This allows medical and surgical teaching-hospital positions to be compared, as they must be to imple-

PROPOSITION 6: *Student preferences satisfying constraint 1 and consultant preferences satisfying constraint 2, but otherwise responsive to a simple rank-ordering, are substitutable. Student preferences satisfying constraints 1 and 3 and otherwise responsive to a simple rank-ordering need not be substitutable.*

Together with Proposition 3, Proposition 6 (which is proved in the Appendix) establishes that stable matchings continue to exist in the Edinburgh market and in the current Cardiff market. The following proposition (also proved in the Appendix) states that the algorithms adapted as described for the Edinburgh market and for the present Cardiff market (without constraint 3) in fact produce stable matchings:

PROPOSITION 7: *The consultant-proposing deferred-acceptance algorithm adapted to preferences that obey constraints 1 and 2 but are otherwise responsive to a simple rank-ordering produces a stable matching, as does the student-proposing algorithm adapted to preferences that obey constraint 1.*

There are some complications that have so far been passed over, the chief of which involves scheduling the jobs each student has been assigned into the August and February starting periods in a way that gives each consultant the right number of house officers in each period. Occasionally (although apparently rarely) the necessary scheduling may be infeasible, as when a number of individuals require a job at a particular time, as a consequence of having arranged their other assignment outside of the region. These situations are resolved at the discretion of the PRAMS committee, typically by editing a job from the preference lists of one of the students (Townsend, 1981 p. 42). Of course this may produce an instability, but it is not one that could be

ment condition 3. Prior to 1973, winter positions in Cardiff were matched before summer positions, but since 1973 they have been matched simultaneously.

predicted in advance, nor can it be acted on following the match, given the rules by which jobs are formally assigned. Although students are invited to indicate the order in which they prefer to fill their medical and surgical positions, these preferences are not honored if they interfere with a feasible scheduling, so there may be some instabilities involving exchange of time slots among groups of students and consultants. I call these instabilities "higher-order" to indicate that they involve coalitions larger than a student and consultant. In the case of scheduling changes, they involve at least two students and two consultants. As noted in Proposition 2, such higher-order instabilities may result from other causes as well, but such higher-order instabilities are likely to be of lesser importance, since they are so difficult to act on. A case in point is the allocation of married couples, which poses the same theoretical difficulties in the United Kingdom as in the United States, but which seems to have had less practical consequence. Whereas an American couple needs to find two jobs in the same location, in the United Kingdom a couple may need to find four jobs in two locations (in two time periods), and the difficulties of identifying a set of such jobs that both the couple and the relevant consultants prefer to those allocated by the match are formidable.

The situation in Cardiff was even more complex during the years in which students were constrained to hold no more than one teaching-hospital position. Aside from the higher-order instabilities just discussed, the combination of constraint 3 with constraint 1 on the preferences may sometimes have the consequence that no stable matchings exist (see Example 4 in the Appendix). In such circumstances, as well as in certain others²⁹ the Cardiff scheme would produce matchings with some instabilities. As near as I can determine (and I do not know how

to make this precise), these instabilities arose relatively rarely.³⁰ What is certain is that they could not be predicted in advance, and so neither the Cardiff system (with or without constraint 3) nor the Edinburgh system allows mutually beneficial "prematch" agreements of the kind discussed in the previous section.³¹

V. Matching by Linear Programming: Cambridge and The London Hospital Medical College

This section considers two closely related matching schemes which do not produce stable matchings in terms of the stated preferences but which are still in use. The first was developed in 1973 at the London Hospital and its Medical College, and the second was developed in 1978 at the University of Cambridge School of Clinical Medicine. Both schemes involve the linear-programming assignment algorithm.

The London Hospital scheme takes as input the rank-orderings of students and consultants.³² Numerical weights are assigned to choices. These are summed for each potential student-consultant pair.

³⁰ I have no information suggesting that constraint 3 was discarded *because* of its potential to produce instabilities; apparently, the facility for automatically accommodating married couples was also eliminated at around the same time, for reasons of simplicity (K. Johns, pers. comm., 23 June 1989).

³¹ Note, however, that in these systems also, students and consultants may assure themselves of being matched by ranking one another first. In this connection, a noteworthy feature of the Cardiff system is that consultants may make their preference list publicly available before the students submit their own preference lists, and in recent years most of them have apparently done so (K. Johns, pers. comm., 3 August 1989). Thus, students will often know where they are in the consultants' rankings before having to submit their own.

³² The students are all graduates of the London Hospital Medical College, and the consultants include all those offering house-officer posts at the London Hospital, together with a group of affiliated hospitals. In a recent year there were approximately 40 posts in London and 70 in regional hospitals. I am indebted to Dr. F. J. Goodwin, the Postgraduate Sub-Dean at the London Hospital Medical College for this information (pers. commun., 31 October, 1984).

²⁹ The full computer code for Cardiff PASHA (as of 1984, including the code for handling constraint 3) is more than 2,000 lines long and creates many special situations, such as those involving filled and unfilled teaching-hospital positions.

A. R. Shah and S. C. Farrow (1976) report that for the first five uses of the algorithm (once in 1973 and twice in 1974 and in 1975) choices 1, 2, 3, and 4 were given weights of 20, 14, 9, and 5, respectively. Thus (1,1) matches received a weight of 40, (1,2) and (2,1) matches each received a weight of 34, and so forth. The resulting weights for each potential student–consultant pair form the basis for the linear-programming assignment problem of matching students to consultants so as to maximize the sum of the matches. Shah and Farrow report that:

The general procedure is for the computer solution to be submitted to the sub-committee of the academic board. On each occasion it has formed a very satisfactory basis for the final solution, although several hand adjustments have been made.³³ [p. 477]

The Cambridge scheme was first implemented in 1978 for posts beginning in February and August 1979. (Students, who normally graduate in December, may apply for positions beginning in February, in August, or for one of each.) Students rank consultants as A, B, C, or unacceptable. "Students may make only two A choices for medicine, and only one of these may be for a medical job at Addenbrooke's, the main teaching hospital. Similarly for surgery. As many B and C choices as they wish are allowed" (D. M. Taylor, pers. comm., 5 June 1987). Consultants rank students similarly (but after learning how the students ranked them, and without a constraint on the number of A rankings.) As in the London scheme, weights are given to each potential match, but in the Cambridge scheme these weights are lexicographic in consultants'

preferences, so consultant–student (A,A) matches have the highest weight, followed by (A,B), (A,C), (B,A), and so forth. As in the London scheme, the matching giving the highest total weight forms the basis of the matching of students and consultants. This matching is also subject to some adjustment (e.g., students are permitted to have only one of their two jobs at Addenbrooke's Hospital). Example 2 proves the following proposition:

PROPOSITION 8: *Both of these schemes may produce unstable matchings.³⁴ Furthermore, they may fail to make (1,1) matches.*

Example 2. For simplicity, consider three consultants, each of whom has only one position to fill, and three students, each of whom needs only one position. Their rank orderings are as follows:

$C_1: s_1, s_2, s_3$	$s_1: C_1, C_2, C_3$
$C_2: s_1, s_3, s_2$	$s_2: C_1, C_3, C_2$
$C_3: s_3, s_1, s_2$	$s_3: C_3, C_2, C_1$

The unique stable matching is μ such that $\mu(C_1) = s_1$, $\mu(C_2) = s_2$, and $\mu(C_3) = s_3$. [This follows since (C_1, s_1) and (C_3, s_3) are both (1,1) matches and so must be included in any stable matching.] However, the London Hospital scheme (with weights as given above) gives μ a weight of 98, while the highest total weight (108) is achieved by the unstable matching ν with $\nu(C_1) = s_2$, $\nu(C_2) = s_1$, and $\nu(C_3) = s_3$. Similarly the Cambridge scheme [with (A,A) matches worth 8, (A,B) worth 7, and so on, down to (C,C) worth 0 for this example] chooses ν (which has a total weight of 20, compared to μ with total weight of 16).

In this example, no individual agent can improve his outcome by changing his stated preference.³⁵ More to the point, even when

³³Shah and Farrow (1976 p. 477) also note that, to adjust the match, the preferences of different individuals may be weighted differently. "[I]n July 1974 the initial solution led to several applicants, who had completed 6 months, not being allocated a second appointment. This made it necessary to rerun the programme with a reduction in weight of newly qualified applicants. This second run achieved the designed outcome."

³⁴That the London scheme may produce unstable matchings was noted by Townsend (1977).

³⁵Actually, this depends on how unacceptable matches are weighted. When unacceptable matches are part of the matching with the highest total weight, they correspond to unmatched students and positions.

all pairs of agents but one organize themselves into (1, 1) matches (as in the example), they cannot be sure of being matched (unless they both rank all other options as unacceptable). Thus, private arrangements are more difficult to make and are less certain than in any of the other matching schemes considered here. Nevertheless, the following parallel to Proposition 5 for priority matching systems applies as well to these linear-programming systems; the proof is left to the reader:

PROPOSITION 9: *It is not a dominant strategy for any agent to submit his true preferences in these linear-programming matching systems. Furthermore, there are multiple equilibria at which all agents submit only a first choice.*

While these systems have some important differences from the failed priority matching systems [as exemplified by the fact that (1, 1) matches are not assured of forming], they have enough significant similarities so that one may wonder how to account for the longevity of the London Hospital and Cambridge schemes. One hypothesis is that the environments in which the markets are conducted differ significantly from other environments: each of these two schemes is for the graduates of a single medical school, on the small end of the range of markets considered here.³⁶ Thus, there may be social and other kinds of pressures that make it difficult to circumvent the formal matching scheme. In this regard S. C. Farrow (pers. comm., 23 October 1984) writes:

Candidates are not obliged to accept allocated posts and have been known to decline; this is of course frowned upon by the scheme and they try hard

to dissuade people from taking such a course.

Similarly, Goodwin (pers. comm., 31 October 1984) adds:

Virtually all candidates accept the posts allocated to them. Indeed, we achieve a match of the candidates' and consultants' first choices in around 70 percent of cases which is obviously satisfactory to all concerned. The remainder nearly always accept the post to which they have been allocated. Of course, we have no legal right to prevent someone from declining a post after it has been allocated to him but this would be considered pretty bad form and the candidates know it.

Thus, in markets of this size and composition, it may be that participation in the matching scheme may be somewhat less voluntary than in larger markets or markets in which many of the agents are not so intimately connected with one another.³⁷

Another hypothesis, in view of the high reported percentage of (1, 1) matches, is that the agents manage to adapt to the system by coordinating among themselves before the formal match or by modifying the rank-orderings they submit. In such a case, the outcome of the match might even be stable. (To test such a hypothesis, it would be necessary to have better information about the submitted rank-orderings than I presently have. However, see Susan Mongell and Roth [1991] for an account of an unstable match-

³⁶They are thus not completely "impersonal" markets, particularly since the most desirable positions are in the associated teaching hospital; and the most desirable house officers are the top students in the class. Since total class sizes are around 100, the key players on both sides of the market have often had the opportunity to get to know one another in the course of the students' medical education.

³⁷B. T. Colvin, the present Postgraduate Medical Sub-Dean at The London Hospital Medical College, writes that "Much of the goodwill in the system relies on the Postgraduate Sub-Dean's personal knowledge of the candidates, consultants and posts, and his ability to impose on both parties the moral obligation to comply with the allocations..." (pers. comm., 10 August 1989). To the extent that agents in this market are obliged or feel obliged to comply, it would of course be unsurprising that unstable matchings and matching procedures can persist: the National Football League draft and the process by which graduates of the U.S. Naval Academy obtain their first assignments (see Roth and Marilda Sotomayor, 1990) are good examples of such markets.

ing procedure for which such data were available; the data gathered for that procedure supported an equilibrium misrepresentation hypothesis of this kind.)

In either case, these matching schemes and the environment in which they operate appear to make prematch coordination both more difficult and less rewarding than do the priority matching schemes discussed in Section III.

VI. Interregional Instabilities and the Current State of Affairs

Students who fail to obtain two positions in the regional markets can participate in a secondary market, called the Safety Net, organized by the Councils for Postgraduate Medical Education,³⁸ which distributes information on unfilled posts and unplaced students. Consultants with unfilled positions may hire senior house officers (instead of preregistration house officers) after a certain date. In 1983, about 25 graduates of U.K. medical schools failed to obtain any preregistration position, in part because some consultants apparently hired senior house officers before the preregistration market had cleared. The incentives for consultants to do so were apparently heightened by the fact that some students would break arrangements made in this market if a more desirable position became available at the last minute (see Henry Yellowlees, 1983; E. D. Acheson, 1984).

In response to these events, a working group was established to study the current market, and their 1987 report (Department of Health and Social Security, 1987) describes the current state of affairs as follows:

...matching arrangements are tending to take place increasingly early in the

clinical years. In some cases, students are matched to posts even before they have entered the final clinical year.... The earlier a student is matched to a post, the greater the chance that for some reason he or she may decide not to fulfil the arrangements but to take some other post instead. Where medical schools run particularly early matching schemes it appears that some Districts not involved in the schemes then advertise their pre-registration posts at an even earlier date in order to try to pre-empt the matching scheme. This has led to some posts being advertised as much as 18 months before their start date. [p. 11]

The report also notes that medical schools should help in:

...ensuring that their unmatched students are made aware that it is unethical, while holding an offer for one post, to accept an offer for another before negotiating release from the prior bargain.... [p. 11]

What seems to be occurring is that, as the centralized matching schemes in individual regions of the National Health Service have unravelled backward in time and been abandoned, the situation in most regions today has come to resemble that of the late 1960's.³⁹ The instabilities that underlie the contemporary problems appear to involve not only instabilities in a given region, but also instabilities between regions.⁴⁰

³⁸The Council for Postgraduate Medical Education in England and Wales has recently been replaced by the Standing Committee on Postgraduate Medical Education (SCOPME). As of 1 April 1989, the responsibility for the Safety Net has passed to the Department of Health (no longer DHSS, social security having been separated from health in mid-1988).

³⁹In another contemporary report, J. H. Gillard and T. H. S. Dent (1988 p. 344) note that "Both matching schemes and free markets with an official start date were reported to be vulnerable to pre-empting. This criticism was conveyed most vigorously from Nottingham and Southampton [both with "free market" decentralized systems], and caused considerable anxiety. Students feared that their colleagues were making private arrangements with consultants, while consultants were keen to avoid missing the more attractive students. If a formal match operates later, students might waste an application if the posts have been covertly allocated by student and consultant agreeing to place each other first in their order of preference."

⁴⁰Instabilities involving positions in other regions can affect even regions with stable regional matching

In view of the experience in the regional markets and in the American market, perhaps the most promising plan to remedy the unraveling of appointment dates and the problems that accompany it would be to replace the patchwork of regional markets with a national market organized around a set of stable procedures (such as those in use in Edinburgh).⁴¹

VII. The Implications for Other Markets

The environment in which the various U.K. markets operate differs in important ways from that of the American market in size, in the number of jobs sought by each student, and in the centralization of authority (at least within a given region). Still, the experience of the various centralized matching schemes considered here allows two very different hypotheses about matching markets which might have been formed on the basis of the evidence of the American market to be rejected.

The first of these hypotheses, which might be called the "pure-transaction-cost hypothesis," is that, because a centralized matching mechanism reduces the high transaction costs found in the chaotic decentralized markets, *any* centralized procedure would obtain high rates of participation. The rapid failure of the priority matching schemes in the regions where they were tried is clear evidence against this hypothesis.

The second of these hypotheses, which might be called the "pure-efficiency hypothesis" (or perhaps the "core hypothesis") is that, in order to achieve high rates of participation, a scheme must produce matchings that do not allow coalitions of *any* size to profit by defecting from the scheme. The

higher-order instabilities that can occur in the Edinburgh (1969) and Cardiff schemes (and which Proposition 2 suggests may be endemic), not to mention the pairwise instabilities that can arise in the linear programming schemes, suggest that this is not the case either.

A more accurate description seems to lie somewhere in between. Centralized matching schemes like the priority matching schemes, which make it easy for pairwise coalitions to defect profitably, experience widespread defection even when the system is endowed with enough authority to require at least pro forma participation. However, orderly participation in a centralized matching scheme appears to be much more likely when the opportunities it presents for defection are rare and difficult to find or when they primarily involve large coalitions.

Another observation that may have considerable generality is that markets of this kind have a propensity to unravel backwards in time, with dates of appointment becoming earlier and earlier. This phenomenon seems to occur in very different kinds of markets. (Indeed, the membership drives of American sororities are called "rush" precisely because they have unraveled in this way [see Mongell and Roth, 1991]. Among the markets presently experiencing this sort of unraveling are some of those for newly graduated lawyers, about which I hope to have more to say in the future.) This suggests that the kind of models considered here may be useful tools with which to explore a wide variety of entry-level labor markets and related matching processes. Centralized markets have been a productive place to begin this kind of study, because they make it relatively straightforward to determine the "rules of the game" in the kind of detail demanded by game-theoretic analysis. However, with the experience gained from studying such markets, it should be possible to study decentralized markets in related ways.⁴²

procedures. Sir James Fraser (pers. comm., 10 July 1987), writing of the Edinburgh PRAMS, notes that "... one of the principles behind the Scheme is that a student is committed to accept the Unit to which he is allotted. Rarely, this formal agreement is broken, more commonly by applicants from outside Edinburgh..."

⁴¹Of course, there may be formidable and perhaps intractable problems of coordination, having to do with different schedules and jurisdictions, involved in setting up such a national market.

⁴²A theoretical question related to the study of decentralized markets has recently been resolved in a paper by Roth and John Vande Vate (1990), which

In closing, a few words are probably in order about the methodology this paper shares with the related empirical studies of matching in Roth (1984a) and Mongell and Roth (1991). The chief analytical tools (stability and strategic equilibrium) are a mix drawn from what has traditionally been called cooperative and noncooperative game theory. Their use together here should help make clear why this is not always a useful distinction, since these two approaches to game theory are complements, rather than substitutes. While the rules of the game must be identified in great detail in order to speak about equilibrium, the stability of a matching may be discussed somewhat independently of the specific rules of the market. One of the phenomena that emerges from these studies is that, when the outcomes are unstable, agents have incentives to change the rules of the game, as when they decide to introduce a centralized matching procedure or to defect from one. In principle, all such decisions could be modeled in terms of some larger, all-encompassing game, and much of the contemporary theoretical literature in game theory takes this point of view. However, this will seldom be an option in modeling complex real systems, whose rules need to be determined by observation (and determining rules by observation will often be subject to uncertainty, since as has been seen, formal rules sometimes turn out to be less than fully binding, while informal unwritten rules may impose real constraints). If game theory is to play as important a role in empirical economics as it already plays in economic theory, increased attention must be paid to modeling complex games whose rules can only be observed imperfectly.

APPENDIX

Proposition 10 below is an impossibility result that strengthens the conclusions of

Proposition 4 and shows that no priority matching scheme always produces stable matchings. An arbitrary priority matching scheme is given by a priority function $f: \mathbf{N} \cup \{x\} \times \mathbf{N} \cup \{x\} \rightarrow \mathbf{N} \cup \{x\}$, where \mathbf{N} is the set of positive integers and x indicates that a match is unacceptable. Thus, if a_{ij} is student j 's rank in consultant i 's ordering (i.e., $a_{ij} = k$ means student j is consultant i 's k th choice) and b_{ji} is consultant i 's rank in student j 's ordering, $f(a_{ij}, x) = f(x, b_{ji}) = x$, and $f(a_{ij}, b_{ji}) \in \mathbf{N}$, where $f(a_{ij}, b_{ji})$ is the priority of the match between i and j . The matching μ_f is created by performing all first-priority matches [$f(a_{ij}, b_{ji}) = 1$], followed by all second-priority matches among those agents not yet matched, and so forth. Note that the function f restricted to acceptable matches must be one-to-one (i.e., $f: \mathbf{N} \times \mathbf{N} \rightarrow \mathbf{N}$ is one-to-one) because, for example, (1,2) matches cannot have the same priority as (2,1) matches, since a given consultant might be part of a (1,2) match with s_1 and a (2,1) match with s_2 . Without loss of generality (by taking a monotone transformation of f if necessary), one may also assume that the function f is onto \mathbf{N} [i.e., that there are values of a_{ij} and b_{ji} for which $f(a_{ij}, b_{ji})$ equals 1, 2, etc., with no gaps]. The impossibility result can now be stated.

PROPOSITION 10: *No priority matching function f always produces stable matches μ_f .*

PROOF:

It will be sufficient to prove the proposition for the symmetric case of one-to-one matching. First observe that if (1,1) matches are not first-priority (i.e., if $f(1,1) \neq 1$) then f does not always produce stable matchings. To see this, suppose (i,j) matches are first-priority, and suppose $j > 1$. Let $a_{21} = i$ and $b_{12} = j$, so C_2 and s_1 are matched at the matching μ_f ; but let $a_{11} = 1 = b_{11}$, so C_1 and s_1 are a (1,1) match. Then μ_f is unstable with respect to C_1 and s_1 , which proves the first observation.

Next observe that if $(i,j) \neq (1,1)$ is second-priority and $i > 1$ then μ_f may be unstable, even if (1,1) matches are first-priority. To see this, let (1,1) matches be first-priority and let C_1 , C_2 , s_1 , s_2 , and s_3 be

shows that a wide class of random processes converge with probability 1 to a stable matching. Some preliminary results on strategic behavior in such markets are contained in Roth and Vande Vate (1991).

such that $a_{11} = 1$, $a_{12} = i > 1$, $b_{11} = 2$, $b_{12} = 1$, $a_{23} = 1$, $b_{21} = j$, and $b_{32} = 1$. Then C_2 and s_3 are matched in the $(1, 1)$ phase, and C_1 , s_1 , and s_2 are not (if $j \neq 1$, let $b_{22} = 1$). Therefore, C_1 and s_2 are matched in the (i, j) phase, and the resulting matching is unstable with respect to C_1 and s_1 , which proves the second observation.

A symmetric argument shows that unstable matchings may result unless $j = 1$ also. However, since $(i, j) \neq (1, 1)$, this completes the proof of the proposition.

A formal model of matching sufficiently general for all the cases covered here is the following. There are two sets of agents; $C = \{C_1, \dots, C_n\}$ and $S = \{s_1, \dots, s_m\}$, namely consultants and students. Each consultant C seeks to fill no more than some number q_C of positions, and each student s seeks to obtain no more than $q_s = 2$ positions. A *matching* is a function from $C \cup S$ into the set of all subsets of $C \cup S$ such that, for every C in C and s in S :

- 1) $\mu(C)$ is contained in S and $\mu(s)$ is contained in C (either set may be empty);
- 2) $|\mu(C)| \leq q_C$ for all C in C ;
- 3) $|\mu(s)| \leq q_s = 2$ for all s in S ;
- 4) s is in $\mu(C)$ if and only if C is in $\mu(s)$.

Each agent A has preferences over sets of agents on the other side of the market that determine a choice function Ch_A as in Section II. Each agent's preferences over matchings are sensitive only to his own part of the matching, so that if μ and ν are matchings such that $\mu(A) = \nu(A)$, then agent A is indifferent between μ and ν .

An agent A has *responsive* preferences if he has a rank-ordering of the individual agents on the other side of the market such that, for any subset T of such agents, $Ch_A(T)$ is the set of the q_A highest-ranked acceptable individuals in T (or all the acceptable individuals in T if there are fewer than q_A). Note that this is a slightly weaker definition than that given in Section I, since this definition deals only with the agents' choice sets and ignores preferences between subsets T that would not arise as choices from a common set. Note also that responsive prefer-

ences are substitutable, as defined in Section II.

The following example proves the second part of Proposition 2, namely that stable matchings need not be in the core, nor even be Pareto optimal, in many-to-many matching with responsive preferences.

Example 3. There are four consultants, each of whom seeks two house officers, and four students, each of whom seeks two positions. The (responsive) preferences of the agents are given by the following rank-orderings of acceptable subsets:

- s_1 : $\{C_1, C_2\}$, $\{C_1, C_3\}$, $\{C_1, C_4\}$, $\{C_2, C_3\}$,
 $\{C_2, C_4\}$, $\{C_3, C_4\}$, $\{C_1\}$, $\{C_2\}$, $\{C_3\}$, $\{C_4\}$
 s_2 : $\{C_2, C_1\}$, $\{C_2, C_4\}$, $\{C_2, C_3\}$, $\{C_1, C_4\}$,
 $\{C_1, C_3\}$, $\{C_4, C_3\}$, $\{C_2\}$, $\{C_1\}$, $\{C_4\}$, $\{C_3\}$
 s_3 : $\{C_3, C_4\}$, $\{C_3, C_1\}$, $\{C_3, C_2\}$, $\{C_4, C_1\}$,
 $\{C_4, C_2\}$, $\{C_1, C_2\}$, $\{C_3\}$, $\{C_4\}$, $\{C_1\}$, $\{C_2\}$
 s_4 : $\{C_4, C_3\}$, $\{C_4, C_2\}$, $\{C_4, C_1\}$, $\{C_3, C_2\}$,
 $\{C_3, C_1\}$, $\{C_2, C_1\}$, $\{C_4\}$, $\{C_3\}$, $\{C_2\}$, $\{C_1\}$
 C_1 : $\{s_4, s_3\}$, $\{s_4, s_2\}$, $\{s_4, s_1\}$, $\{s_3, s_2\}$, $\{s_3, s_1\}$,
 $\{s_2, s_1\}$, $\{s_4\}$, $\{s_3\}$, $\{s_2\}$, $\{s_1\}$
 C_2 : $\{s_3, s_4\}$, $\{s_3, s_1\}$, $\{s_3, s_2\}$, $\{s_4, s_1\}$, $\{s_4, s_2\}$,
 $\{s_1, s_2\}$, $\{s_3\}$, $\{s_4\}$, $\{s_1\}$, $\{s_2\}$
 C_3 : $\{s_2, s_1\}$, $\{s_2, s_4\}$, $\{s_2, s_3\}$, $\{s_1, s_4\}$, $\{s_1, s_3\}$,
 $\{s_4, s_3\}$, $\{s_2\}$, $\{s_1\}$, $\{s_4\}$, $\{s_3\}$
 C_4 : $\{s_1, s_2\}$, $\{s_1, s_3\}$, $\{s_1, s_4\}$, $\{s_2, s_3\}$, $\{s_2, s_4\}$,
 $\{s_3, s_4\}$, $\{s_1\}$, $\{s_2\}$, $\{s_3\}$, $\{s_4\}$.

Each agent's preferences over individuals can be read from the last four (singleton) entries in his preference list P over sets. The matching μ that matches each agent to his fourth-choice set of agents [emphasized in boldface in the preferences; i.e., $\mu(s_1) = \{C_2, C_3\}$, $\mu(C_1) = \{s_3, s_2\}$, etc.] is stable. To see this, note that for each s_i , all improvements on $\mu(s_i)$ involve consultant C_i , but C_i is not interested in dealing with s_i alone, since s_i is C_i 's last-choice individual. However, μ is not in the core and is not Pareto optimal, since it is dominated by the matching μ' that gives each agent his third-choice set of agents.⁴³

⁴³In each case, the responsive preferences have been chosen so that an agent prefers to be matched with the set consisting of his first- and fourth-choice

To adapt the example to the requirement that students must obtain one medical and one surgical position, suppose C_1 and C_3 offer surgical positions, while C_2 and C_4 offer medical positions. Then, the student preferences given above can be modified by simply deleting from the preference lists the unacceptable sets $\{C_2, C_4\}$ and $\{C_1, C_3\}$, which leaves the conclusion of the example unchanged. Similarly, by deleting the set $\{s_1, s_2\}$ from the preferences of C_4 (who might be a urological surgeon from Edinburgh), we obtain the kind of substitutable preferences that result when a gender quota is invoked.

Proposition 3 (and therefore the first part of Proposition 2) is proved next.

PROPOSITION 3: *In the many-to-many matching model in which all agents have substitutable preferences, the set of stable matchings is nonempty.*

The proof will use the following algorithm.

Step 1: Each C makes offers to every s in the set $Q(C, 1) = \text{Ch}_C(S)$.

...

Step k : (i) Each s rejects any offers received so far that are not in the set $\text{Ch}_s(O(s, k-1))$, where $O(s, k-1)$ is the set of offers s has received in steps $1, \dots, k-1$ and not yet rejected by the end of step $k-1$. (ii) Each C who has received at least one rejection in part (i) of step k and who now has (nonrejected) offers outstanding to the students in the set $N(C, k)$, and has been rejected in steps $1, \dots, k$ by the students in the set $R(C, k)$, makes (or renews) offers to his most preferred set of students $Q(C, k)$ in the collection of sets $\{Q \subset S \setminus R(C, k) \text{ such that}$

$Q \text{ contains } N(C, k)\}$. (Subtraction of sets is denoted by \setminus .) That is, C 's outstanding offers at the end of step k include all those issued at previous steps and not yet rejected and none of those that have already been rejected. (iii) The algorithm stops at any step $k = T$ at which no rejections are issued, and the resulting matching is μ such that $\mu(C) = N(C, T)$ for each C in C .

The proof, which involves showing that the matching μ resulting from the algorithm is stable (as defined in Section II) when preferences are substitutable, makes use of the following lemmas. The first says that the requirement that consultants keep open all offers that have not been rejected does not constrain them: at each step, they issue offers to their choice set from among those that have not yet rejected them. (The lemmas, like the algorithm, are stated as if preferences are strict so that there is always a unique choice set. This assumption is for notational convenience only; if it were relaxed, it would be necessary to denote a choice set, meaning one among the collection of most-preferred sets, instead of the choice set as below.)

LEMMA 1: *For each step $k = 1, \dots, T$ and each C in C ,*

$$Q(C, k) = \text{Ch}_C(S \setminus R(C, k)).$$

PROOF:

For $k = 1$, $R(C, 1) = \emptyset$, so $Q(C, 1) = \text{Ch}_C(S \setminus R(C, 1))$. Suppose now, inductively, that $Q(C, j) = \text{Ch}_C(S \setminus R(C, j-1))$ for $j = 1, \dots, k-1$. Then, if s is in $N(C, k)$, s is in $Q(C, k-1) = \text{Ch}_C(S \setminus R(C, k-1))$; but $\{S \setminus R(C, k-1)\}$ contains $\{S \setminus R(C, k)\}$, and s is an element of $\{S \setminus R(C, k)\}$, so substitutability implies that s is an element of $\text{Ch}_C(S \setminus R(C, k))$ [i.e., that $\text{Ch}_C(S \setminus R(C, k))$ contains $N(C, k)$]. Therefore, $Q(C, k) = \text{Ch}_C(S \setminus R(C, k))$, which completes the proof by induction.

The next lemma says that, no matter what the sequence of offers a student receives, he

individuals rather than his second and third choices. This is not a consequence of responsiveness; it is easy to check that reversing this preference would still leave the preferences responsive.

never regrets having rejected earlier offers when he discovers what the later offers are.

LEMMA 2: *For each s in S , if the algorithm stops at step T ,*

$$\begin{aligned}\mu(s) &\equiv O(s, T-1) \\ &\equiv \text{Ch}_s(O(s, T-1)) \\ &= \text{Ch}_s\left(\bigcup_{k=2}^T O(s, k-1)\right).\end{aligned}$$

PROOF:

Suppose that C is an element of $\text{Ch}_s(\bigcup_k O(s, k-1))$, and let k be such that C is an element of $O(s, k-1)$. Then by substitutability, C is an element of $\text{Ch}_s(O(s, k-1))$. Therefore, s does not reject C at any step of the algorithm, so C is an element of $O(s, T-1)$, and $\text{Ch}_s(\bigcup_k O(s, k-1))$ is a subset of $\mu(s)$. However, $\mu(s) = \text{Ch}_s(O(s, T-1))$ cannot be strictly preferred to its subset $\text{Ch}_s(\bigcup_k O(s, k-1))$, and so when preferences are strict the two sets must be equal (and when preferences are not strict the choice sets can always be selected so that the two sets are equal).

The proof of Proposition 3 is now simple.

PROOF OF PROPOSITION 3:

The lemmas imply that $\mu(s) = \text{Ch}_s(\mu(s))$ for all students s , and $\mu(C) = \text{Ch}_C(\mu(C))$ for all consultants C . Now consider a student s and consultant C , not matched to one another at μ , such that s is an element of $\text{Ch}_C(\mu(C) \cup s)$. Lemma 1 implies that, during the course of the algorithm, C made an offer to s and was rejected. Then, Lemma 2 implies that $\text{Ch}_s(\mu(s) \cup C) = \mu(s)$. Therefore, μ is stable.

The above proof demonstrates that the set of stable matchings is nonempty in many-to-two matching with substitutable preferences. Proposition 6 states that preferences constrained to obey constraints 1 or 2 described in Section IV are substitutable,

while those constrained to obey 1 and 3 are not.

PROOF OF PROPOSITION 6:

First consider an agent A with quota q_A ($= 2$ if A is a student) whose preferences are responsive except insofar as they satisfy either constraint 1 (if A is a student) or 2 (in which case A must be a consultant surgeon). That is, A has a rank-ordering over the agents in the opposite set, which can be represented as a set of the form $B = B_1 \cup B_2$, and A finds it unacceptable to be matched to any subset S of B that contains more than one member of B_2 (and, if A is a student, more than one member of B_1). Thus, for any subset T of B , $\text{Ch}_A(T)$ is a set consisting of the q_A highest-rank acceptable members of T (or all of them if there are fewer than q_A), providing that these contain no more than one member of B_2 (or B_1), and otherwise it is a set consisting of the highest-ranked member of $B_2 \cap T$ and the $q_A - 1$ highest-ranked acceptable members of $B_1 \cap T$ (or all of them if there are fewer than $q_A - 1$). Now it is easy to check that, for any t in B_1 or B_2 and $t' \neq t$ in B_1 or B_2 , if t is in $\text{Ch}_A(T)$ then it is also in $\text{Ch}_A(T - t')$. This completes the proof of the proposition for the case of preferences satisfying constraints 1 or 2.

Now consider a student s whose preferences satisfy constraints 1 and 3 but are otherwise responsive to a rank-ordering over individual consultants, and let this rank-ordering be C_1, C_2, C_3, C_4 , where C_1 and C_3 are teaching-hospital positions in medicine and surgery, respectively, and where C_2 and C_4 are nonteaching hospital positions in medicine and surgery, respectively. Then, it is possible to have $\text{Ch}_s(\{C_1, C_2, C_3, C_4\}) = \{C_1, C_4\}$ but $\text{Ch}_s(\{C_2, C_3, C_4\}) = \{C_2, C_3\}$, which does not contain C_4 , so these preferences are not substitutable. This completes the proof of Proposition 6.

PROOF OF PROPOSITION 7:

Recall that each consultant in the deferred-acceptance algorithm as modified at Edinburgh submits a rank-ordering of individual students. Following a rejection in the

algorithm, a consultant extends an offer to the highest-ranked (eligible) student who has not yet received an offer from him, where only male students may be eligible if the consultant is a surgeon who has exercised his option to limit the number of female house officers. Each student has submitted separate lists of medical and surgical positions and rejects all but the best offer in each category.

It is immediate from the above description of the algorithm and from Proposition 6 that this conforms to the version of the algorithm used here to prove Proposition 3, if the consultants have responsive preferences that are lexicographic in their lower-ranked (more preferred) candidates (e.g., a consultant C whose rank-ordering is $s_1, s_2, s_3, s_4, \dots$ must prefer $\{s_1, s_4\}$ to $\{s_2, s_3\}$ in order for the algorithm to correspond to that used to prove Proposition 3). Thus, if the consultants have such preferences, the matching is stable. However, suppose they have responsive preferences that are not lexicographic in this way (e.g., suppose the above consultant C prefers $\{s_2, s_3\}$ to $\{s_1, s_4\}$). If there were a student s such that the resulting matching was unstable with respect to (s, C) , then the matching would be unstable with respect to *any* preferences that are responsive to C 's rank-ordering of individual students. Since this cannot be, the resulting matching is stable.

The following example shows that the set of stable matchings may be empty when student preferences obey both constraints 1 and 3 from Section IV:

Example 4. Consider a market that includes four students applying to consultants MT_1 , ST_1 , ST_2 , SNT , MNT , where M stands for a medical position, S for a surgical position, T for a teaching-hospital position and NT for a nonteaching-hospital position. For simplicity, each consultant seeks only one student. Each student seeks one medical and one surgical position and may not hold more than one teaching-hospital position. The preferences over individual students and positions are given by the following rank

orderings:

s_1 : SNT, ST_2, MT_1	MT_1 : s_1, s_2
s_2 : MT_1, ST_1	ST_1 : s_2, s_3
s_3 : ST_1, SNT	ST_2 : s_1, s_4
s_4 : ST_2	SNT : s_3, s_1, s_2
	MNT : s_1, s_2

To see that every matching μ is unstable in this example, first suppose that μ is stable and that $\mu(SNT) \neq s_1$. Stability implies $\mu(SNT) = s_3$, which implies $\mu(ST_1) = s_2$, which implies $\mu(MT_1) = s_1$, which implies that μ is unstable with respect to (s_1, ST_2) , a contradiction. Thus, if μ is stable, $\mu(SNT) = s_1$. However, this implies $\mu(ST_1) = s_3$, which implies $\mu(MT_1) = s_2$, which implies that μ is unstable with respect to (s_1, MT_1) , which is the contradiction needed to prove that no matching is stable.

Sorority Rush as a Two-Sided Matching Mechanism.

By SUSAN MONGELL AND ALVIN E. ROTH*

The history and organization of the membership recruitment process of American sororities is studied. Like entry-level labor markets studied previously, this process experienced failures that led to the adoption of a centralized matching procedure in which a matching is determined on the basis of preference lists submitted by the agents. Analysis of the rules of the match and of preference lists from 21 matches reveals an unstable matching procedure that gives agents incentives to behave strategically. The analysis also shows how the agents act on these incentives and how the resulting strategic behavior has contributed to the longevity of the matching system and to the stability of the resulting matches. (JEL C78, D00, J41)

This paper concerns the formal process by which women at American universities join the social organizations called sororities. The history of this process, of the problems it has encountered, and how it has evolved to meet them, have striking similarities to (as well as important differences from) the history and organization of the American labor market for medical interns (see Roth, 1984a) and the several similar entry-level labor markets for physicians in the United Kingdom (see Roth, 1991). Thus, by studying this process, we hope to learn more about other matching processes and hope to assess the generality of various hypotheses about them.

In the medical labor markets, competition for newly graduating medical students and for desirable positions caused the dates at which appointments were finalized to unravel in time, so that by the 1940's in the United States and by the 1960's in the United Kingdom, postgraduation employ-

ment was often arranged well over a year (and sometimes over two years) in advance of graduation. Similarly, by the latter part of the last century, entry into fraternities and sororities, initially reserved for college seniors, had worked its way backward to the freshman class, and in some cases membership was arranged well before matriculation. (This aspect of the competition for members appears to be the origin of the term "rushing," as these membership drives are now called.)

Largely in response to the problems arising out of this kind of unraveling, the parties involved in the different medical labor markets eventually agreed to try a variety of centralized matching procedures, in which participants would not sort themselves out individually but would instead submit rank-orderings of their choices to a central clearinghouse, which would use this information to match students to jobs. Similarly, about 60 years ago, the umbrella organization of American sororities recommended that a centralized procedure be used to match students to sororities on college campuses.

The basic mechanism used to process the rank-orderings submitted by students and sororities is called the "preferential bidding system" (PBS), and it remains in use today. This paper analyzes the PBS algorithm, the setting in which it is employed, the incentives it gives to students and sororities, and the matchings that result.

*Department of Economics, University of Pittsburgh, Pittsburgh, PA 15260. Because of the requirement that the campuses should remain anonymous, we are unable to thank by name the many administrators without whose help this study could not have proceeded. We have received helpful comments from Patty Beeson. This work has been supported by grants from the Alfred P. Sloan Foundation, the National Science Foundation, and the Office of Naval Research.

This analysis reveals that the PBS algorithm is different in an important way from the algorithm around which the American medical market is organized and the algorithms around which some of the most successful and long-lived of the medical markets in the United Kingdom are organized. Those other algorithms have the property that they produce matchings that are *stable*, in the sense that, for markets of the kind considered here, they are in the core of the market, when agents state their true preferences.¹ The PBS algorithm does not have this property: the matchings it produces are stable in the preliminary market in which the algorithm operates, but they are not in the core of the market as a whole. Furthermore, for many configurations of preferences, the algorithm fails to produce a matching at all.

Nevertheless, when we examine data from 21 rushes on four campuses,² we observe only one such failure. A large part of the explanation appears after further examination of the data, which makes clear that the submitted preferences are unlikely to correspond to the true full preferences of the students. Instead, the observed pattern of preferences corresponds to what we would expect to see if the students respond strategically to the incentives induced by the matching procedure. When students do respond this way, the PBS procedure will not fail, and the resulting matching will be stable.

I. A Brief History

The first Greek-letter sorority was founded in 1870 (James Brown, 1920). A sorority may be present on campuses throughout the United States, and each

sorority location is called a chapter. In the literature of fraternities and sororities, from which we will sometimes quote, "fraternity" is used to mean either the all-male or the all-female social organizations, while "sorority" refers to the all-female organizations. Many sororities have joined a national organization, the National Panhellenic Conference (NPC), which consisted of 26 member sororities as of 1985. On each campus, all NPC sorority chapters are members of a College Panhellenic Council, the local governing body that determines rushing regulations.

Brown (1920 p. 14) described the early competition for members:

In the early days of the fraternities only seniors were admitted to membership, but the sharp rivalry for desirable men soon pushed the contest into the junior class, and so on down, until at some colleges it scarcely stops at the academy. The general rule is, however, that members shall be drawn from the four undergraduate classes. ... As the colleges usually open about the middle of September, the campaign for freshmen is then commenced and lasts until Christmas, when each chapter has secured its most desirable candidates. Where there is great rivalry, however, initiations take place all year round.

Earlier appointment dates were not the only evidence of competition:

Membership in two fraternities has been a source of trouble and vexation. It is almost universally forbidden. When it occurs between two chapters of different fraternities located at the same college, and a student leaves one and joins the other, it is termed "lifting," and such disloyalty is usually followed by expulsion. ... All of the fraternities now forbid this, although many years ago it was not uncommon. [Brown, 1920 pp. 15-16]

An early attempt to resolve these problems occurred in 1891, when the first meeting of sororities, in what was then called the

¹These markets involve many-to-one matching, since each student joins at most one sorority. In markets of many-to-many matching, stable matchings need not be in the core (see Roth, 1991).

²The data available to us come from campuses in which, loosely speaking, there is a "buyers' market" for sorority positions. We will discuss differences expected in "seller's markets."

Inter-Sorority Conference, was called to discuss intersorority cooperation. Although resolutions were passed decrying the practice of "lifting" and calling for the "abolition of the practice of pledging and initiating preparatory students" (National Panhellenic Council, 1983 p. 5), this had little effect. Similar sentiments were expressed in subsequent years, to equally little effect, and by 1928 the NPC was ready to turn to a centralized system of matching, and the first mention of the preferential bidding system appears.³ Francis Shephardson (1930 p. 8) reviews the events leading up to this:

The constant rivalry among chapters and the multiplication of fraternities have led in many cases to an indiscriminate scramble for members at the beginning of each year. Both fraternities and the colleges have perceived the danger of this sort of "rushing," as the contest for members is called, and are giving the subject thoughtful consideration. The deferred pledging of students until a fixed date and the deferred initiation of pledged members until they have completed a prescribed portion of their college course or secured a predetermined grade are both becoming common. Such procedure is in striking contrast with earlier custom in some of the larger Western and Southern colleges where, the preparatory schools being intimately connected with the colleges, "preps" were not only pledged, but initiated before they entered the college proper, or with the reprehensible custom which prevails in some places, where pledge pins are given out to boys in the high school or even in the grammar grades.

The preferential bidding system has since been incorporated into the recruiting activities of sororities, as described next.

II. The Organization of Recruiting Activities

The activities of a sorority seeking new members are called rush.⁴ There are two types of rush: formal rush and continuous open bidding. The NPC recommends "one formal rush period per year, held in the early fall, as close as possible to the start of the academic year, and conducted in as short a period of time as possible" (National Panhellenic Conference, 1979 p. 29).

Women participating in formal rush ("rushees") attend a sequence of parties designed to enable rushees and sororities to "narrow their choices gradually" (National Panhellenic Conference, 1979 p. 35). The first parties are "open houses" in which all sororities issue invitations to all rushees. In subsequent rounds, sororities issue invitations selectively. "Panhellenic strongly urges each sorority to re-invite ... only those rushees they are seriously considering for membership. This will enable both the rushee and the sororities to know 'how they stand' early in the formal rush period" (National Panhellenic Conference, 1979 p. 46). In each round, the number of sororities a rushee can attend is reduced. A rushee who receives more invitations than the number of parties permitted in a given round must decline, or "regret," the excess invitations. In the last round of invitational parties, the "preference parties," a rushee is usually permitted to attend only two or three parties. "Panhellenic strongly urges each sorority to invite *only* those rushees to the preference party to whom they will definitely issue a bid" (National Panhellenic Conference, 1979 p. 46).

After the last preference party, rushees indicate their sorority preferences on a card, which they sign. (A rushee who lists only a single sorority is said to have *suicided*.) Sororities similarly submit a preference or-

³See *National Panhellenic Review* (1985 p. 5) for a dated list of motions passed.

⁴The process described next is the recommended procedure appearing in the *"How To" Manual for College Panhellenics* (National Panhellenic Conference, 1979). While these rush procedures are not required, the essential features have been incorporated in each of the campuses we contacted.

dering of rushees. Once all preferences have been submitted, the PBS algorithm matches rushees to sororities.

Each sorority is eligible to be matched to up to *quota* (q) rushees during formal rush, where *quota* is "the number of rushees accepting at least one invitation to the first round of invitational parties, divided by the number of participating fraternities"⁵ (National Panhellenic Conference, 1979 p. 37).

Following the completion of the PBS algorithm, there is one more step in the formal rush process, which officially exists in two slightly different forms (and which in practice seems to vary somewhat more from campus to campus). Under the "quota-only" procedure, any sorority that has been assigned some number p of rushees by the PBS algorithm with $p < q$ is allowed to extend one additional set of at most $q - p$ bids to unmatched rushees. Under the "quota-plus" procedure, any sorority that has not been assigned q new members under the PBS algorithm or whose total membership $m + p$ (including the p new members) is below the total allowable chapter size, T (which is the same for all sororities on a given campus), is allowed to extend one additional set of at most $\max\{q - p, T - (m + p)\}$ bids to unmatched rushees. Rushees who were unmatched by the PBS algorithm are free to accept at most one of the bids they receive or to decline all such bids.

The results are announced on "pledge day," marking the end of formal rush. A rushee who enters formal rush by signing a preference card but who subsequently declines to join a sorority to which she has been matched, is not permitted to join another sorority for one year.

Continuous open bidding begins immediately after the close of formal rush. During continuous open bidding, any sorority that

has not received q new members or that has received q new members but is nevertheless below the total allowable chapter size is allowed to recruit additional members by simply extending them invitations to join. At this stage, sororities are not restricted to make a single set of bids but may recruit continuously until their membership reaches T (or, in the case of sororities whose initial membership m was greater than $T - q$, until they have recruited q new members).

This recruitment and matching process resembles those of the centralized medical labor markets (Roth, 1984a, 1991) mentioned in the Introduction: an information gathering period is followed by a centralized matching algorithm, which is followed by a decentralized "after-market." In the case of the medical labor markets, analysis of the matching algorithms is critical to understanding the matching process as a whole. We turn now to a detailed description of the PBS algorithm.

Rushees submit a "preference card" listing the sororities they would be willing to join, in order of preference. Sororities submit a "bid list" of rushees whom they would be willing to have as members. While a rushee can join no more than one sorority, every sorority is able to extend at least q (quota) invitations for new members through the formal rush process. Beyond the first-quota names, sororities list rushees in order of preference. These preference lists are used by the PBS algorithm to assign rushees to sororities. The instructions in Table 1 are from the manual "*How To*" for *College Panhellenics* (National Panhellenic Conference, 1979 pp. 41–2). These instructions are incomplete and contain ambiguous phrases, such as "This process is repeated as long as there is any possibility of a rushee receiving a bid from the fraternity of her first choice" and "When it becomes apparent that a rushee will not receive a bid from the fraternity of her first choice..." The NPC does have a pamphlet explaining the instructions of the PBS algorithm via an example to be conducted in a workshop. This example still does not handle some of the contingencies that may arise during an actual PBS execution.

⁵If this number is not an integer, it is rounded either up or down at the discretion of the individual supervising the rush. Quota can be rounded down without leaving some students unmatched, since rushees sometimes drop out of the formal rush process after the first round of invitational parties.

TABLE 1—SORORITY RUSHING INSTRUCTIONS:
THE PREFERENTIAL-BIDDING-SYSTEM ALGORITHM

Bid Lists:

1. At a specified time, each fraternity files with the Panhellenic Executive a list of women it wishes to bid.
 - a. Lists are in duplicate; one copy is used in bid matching, the other is returned to the chapter when the bid matching is completed.
 - b. The fraternity bid list should be on paper ruled into three columns:
 - Left-hand column—List in alphabetical order of fraternity's first choices up to the limit of quota.
 - Right-hand column—List in order of preference the fraternity's additional choices which may number as many as the chapter wishes to submit.
 - Center column—Is left blank, as this is the column in which the matched bids are entered.

As a bid is matched, the rushee's name is crossed off every fraternity's first or second list. Her name is entered in the center column of the fraternity list of the group to which she is being pledged.
2. Along with its bid lists, each fraternity brings to Panhellenic enough formal bids (in envelopes) for each woman to be pledged. These formal bids are to be addressed after bid matching is completed.

Procedure for Matching Bids:

1. Persons matching bids include the reader, the tabulator, and one alumna handling the bid list from her fraternity. Undergraduates are not to participate in bid matching.
2. Before bid matching begins, names of all rushees who chose not to sign a preference card should be crossed off all preference lists, and those lists adjusted to fill the space of these women.
3. Mechanics:
 - a. After alphabetizing the preference cards, the reader calls the rushee's name and her first choice. If the fraternity of her first choice has given her a bid on its first bid list, it is a matched bid, and all others should cross her from their list. If the rushee's name is not on the fraternity's first bid list, her preference card is temporarily laid aside. Names of rushees who list only one preference and are unmatched at the end of the first reading should be crossed off all other bid lists and their cards laid aside.
 - b. Each time a name is crossed off a fraternity's first bid list, if openings in the fraternity's pledge quota remain, a name from the fraternity's second bid list is added, in the listed order, to the bottom of the unmatched names remaining on the first list. *The number of unmatched names on the adjusted first bid list and the number of those pledged must always equal quota* (unless a chapter has run out of names to add from its second bid list).
 - c. The cards laid aside in step "a" are read again according to the first choice of the rushee. This process is repeated as long as there is any possibility of the rushee receiving a bid from the fraternity of her first choice.
 - d. Those cards remaining are those of rushees whose names are on the second bid list of the fraternities of their first choice.
 - e. When it becomes apparent a rushee will not receive a bid from the fraternity of her first choice, a rushee's second choice is then matched, if possible, in the above manner.
 - f. Any remaining cards are then read according to the rushee's third choice and the same procedure followed.
 - g. The tabulator reads the results, and all bid lists are reviewed for accuracy.
 - h. Unmatched bids—If a rushee's preference card has failed to match for a bid, the Panhellenic Executive may contact the rushee and ask if she will accept a bid from a fraternity not previously listed among her choices, if this other fraternity has her name on one of their bid lists. Any rushee not bid by any of her preference choices is eligible at any future time for rushing and pledging by any fraternity.

Unfilled Quotas—If a fraternity has failed to fill its quota through this bid matching in formal rush, it may be contacted by the Panhellenic Executive to ask if the fraternity wishes to extend a bid to anyone not originally on its bid lists.

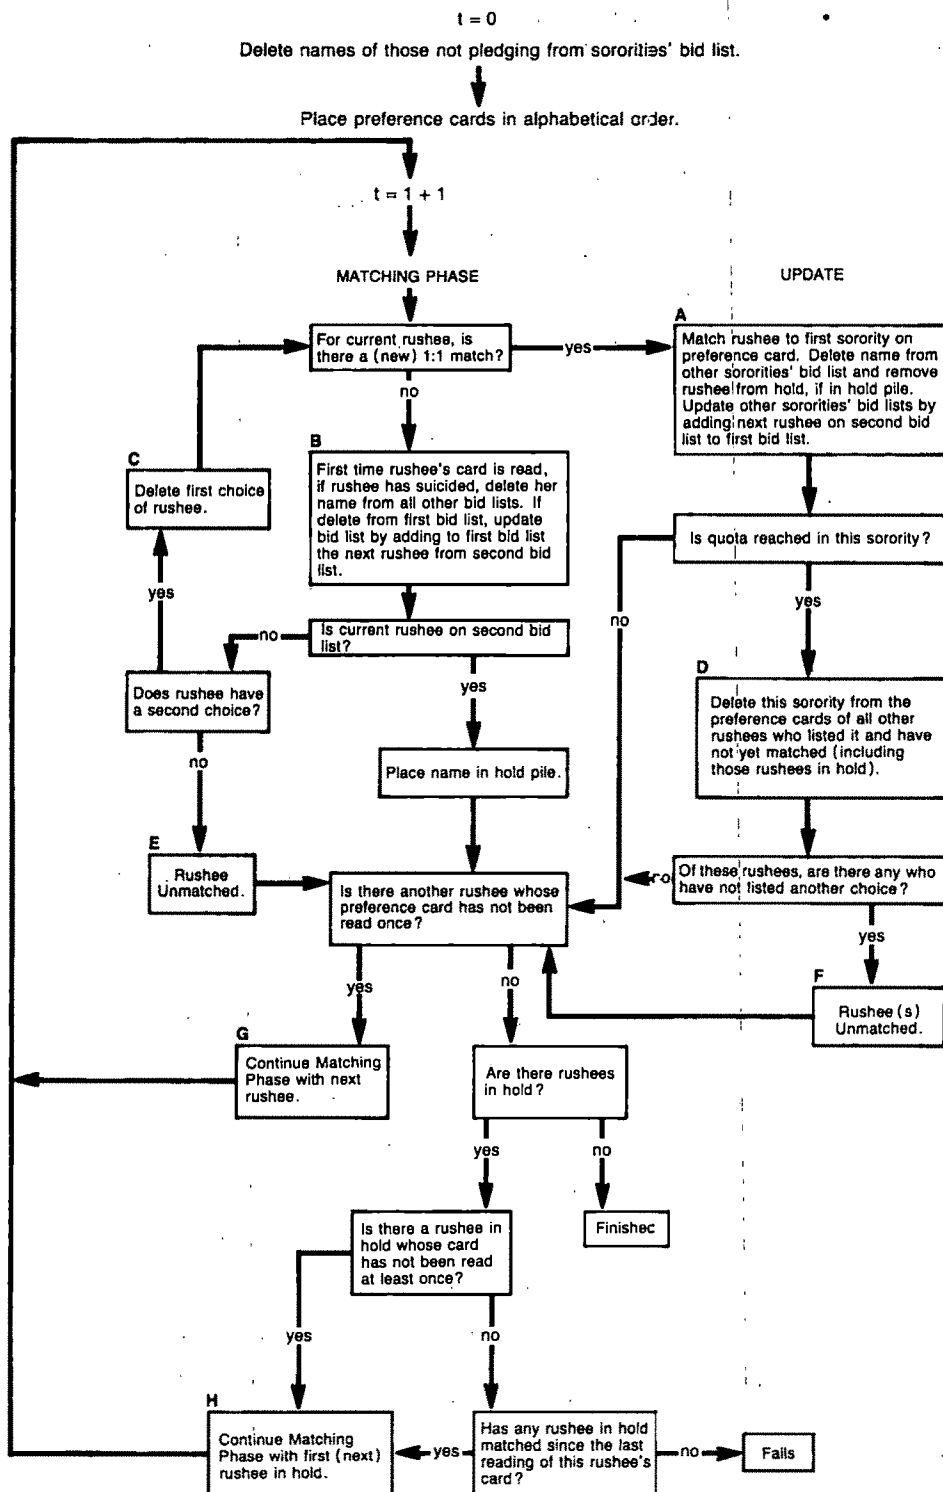

FIGURE 1. PBS-ALGORITHM FLOW CHART

When the instructions given for the PBS algorithm do not indicate what should be done with those rushees whose cards have been "laid aside," we will say that the algorithm "fails."⁶ When we examine the data, it will be seen that, in practice, the PBS algorithm very seldom fails. Indeed, the individuals in charge of administering the algorithm on each of the campuses from which our data are drawn were all initially unaware of the possibility of this kind of failure.⁷

Figure 1 is a flow chart of the PBS algorithm. No such flow chart is found in the sorority literature: this was compiled from both the literature mentioned above and interviews with individuals charged with supervising the matching process on some of the campuses contacted. The original bid list (before any rushees who have not signed a preference card have been deleted) is employed at step $t = 0$. Each time a rushee's preference card is read, t increases by 1.

The final step of the formal rush procedure, during which one set of additional bids may be made (see item h in Table 1 for one variation) has been omitted from the flowchart. Unlike the operation of the algorithm, such additional bids need input from the participants in addition to their initial preference lists. We will consider any such additional bids when we analyze the aftermath of the algorithm.

III. A Formal Model

The first elements of our formal model are two finite and disjoint sets of sororities

⁶For example, consider the case of two rushees and two sororities with $q = 1$. If rushee r_1 ranks sorority S_2 before S_1 , rushee r_2 ranks S_1 before S_2 , sorority S_1 ranks r_1 before r_2 , and S_2 ranks r_2 before r_1 , then both rushees will remain in hold, and the algorithm will fail.

⁷When subsequently presented with examples contrived so as to cause the algorithm to fail, these individuals suggested a variety of ad hoc procedures for restarting the algorithm and completing the matching procedure. Therefore, in the flow chart (Fig. 1), the box labelled "fails" can be viewed as a point in the algorithm in which the implementation would be different on different campuses.

and of rushees, $S = \{S_1, \dots, S_n\}$ and $R = \{r_1, \dots, r_m\}$, respectively. Each rushee has preferences over the sororities, and each sorority has preferences over the rushees. We will assume that these preferences are complete and transitive, with $P(S) = r_1, r_2, S, r_3, \dots$ denoting that sorority S prefers to enroll r_1 rather than r_2 , that it prefers to enroll either one of them rather than leave a position unfilled, and that all other rushees are unacceptable, in the sense that S prefers to leave a position unfilled rather than filling it with, say, rushee r_3 . Similarly, $P(r) = S_2, S_1, S_3, r, \dots$ represents the preferences of rushee r , indicating for example that the only positions the rushee would accept are those offered by S_2, S_1 , and S_3 , in that order. Sorority S is *acceptable* to rushee r if r prefers to be matched to S rather than to remain unmatched, and rushee r is *acceptable* to sorority S if S prefers to have r as a member rather than to leave a position unfilled.

The number of positions each sorority can fill during formal rush is q (quota). An outcome of the PBS algorithm is a matching of rushees to sororities, such that each rushee is matched to at most one sorority and each sorority is matched to at most q rushees. After formal rush (i.e., during the continuous open bidding which follows), each sorority S_k may have a different quota q_k , depending on its membership prior to the start of formal rush and on how many new members it has been matched to during formal rush.

A rushee who is not matched to any sorority will be modeled as "matched to herself," and a sorority with some number of unfilled positions will be matched to itself in each of those positions. A rushee is matched to a given sorority if and only if the sorority is matched to that rushee. To give a formal definition, first define, for any set X , an *unordered family of elements* of X to be a collection of elements, not necessarily distinct. Thus, an element of X may appear more than once, which distinguishes an unordered family from a subset of X .

Definition: A matching μ is a function from the set $S \cup R$ into the set of unordered

families of elements of $S \cup R$ such that:

- 1) $|\mu(r)| = 1$ for every rushee r and $\mu(r) = r$ if $\mu(r) \notin S$;
- 2) $|\mu(S)| = q$ for every sorority S , and if the number of rushees in $\mu(S)$, say p , is less than q , then $\mu(S)$ contains $q - p$ copies of S ;
- 3) $\mu(r) = S$ if and only if r is in $\mu(S)$.

Thus, $\mu(r_1) = S$ denotes that rushee r_1 is enrolled at sorority S at the matching μ , and $\mu(S) = \{r_1, r_3, S, S\}$ denotes that sorority S , with $q = 4$, enrolls rushees r_1 and r_3 and has two positions unfilled. (When sororities have different quotas, q_k replaces q for each sorority S_k .)

Each rushee's preferences over alternative matchings correspond exactly to her preferences over her own assignments at the two matchings. While we have described sororities' preferences over rushees, when q is greater than 1, each sorority must be able to compare groups of rushees in order to compare alternative matchings, and we have yet to describe the preferences of sororities over groups of rushees. (Until we have described sororities' preferences over matchings, our model will not be a well-defined game.)

The simplest assumption connecting sororities' preferences over groups of rushees to their preferences over individual rushees is one insuring that, for example, if $\mu(S)$ assigns sorority S its third- and fourth-choice rushees, and $\mu'(S)$ assigns it its second- and fourth-choice rushees, then sorority S prefers $\mu'(S)$ to $\mu(S)$. Specifically, let $P^\#(S)$ denote the preference relation of sorority S over all assignments $\mu(S)$ it could receive at some matching μ . A sorority S 's preferences $P^\#(S)$ will be called "responsive" to its preferences $P(S)$ over individual rushees if, for any two assignments that differ in only one rushee, it prefers the assignment containing the more preferred rushee, as described formally in the following:

Definition: The preference relation $P^\#(S)$ over groups of rushees is responsive [to the

preferences $P(S)$ over individual rushees] if, whenever $\mu'(S) = \mu(S) \cup \{r_k\} \setminus \{\sigma\}$ for σ in $\mu(S)$ and r_k not in $\mu(S)$, then S prefers $\mu'(S)$ to $\mu(S)$ [under $P^\#(S)$] if and only if S prefers r_k to σ [under $P(S)$]. (Subtraction of sets is denoted by \setminus .)

Note that S may be indifferent between distinct assignments $\mu(S)$ and $\mu'(S)$ even if S has strict preferences over individual rushees.

A matching μ is *individually irrational* if $\mu(r) = S$ for some rushee r and sorority S with either r unacceptable to S or S unacceptable to r . Such a matching is *blocked* by the unhappy agent. This terminology reflects that the rules allow every agent to withhold her (or its) consent from such a match. Similarly, a sorority S and rushee r will be said to *block* a matching μ together if they are not matched to one another at μ but would both prefer to be matched to one another rather than to (one of) their present assignments. That is, μ is blocked by the sorority-rushee pair (S, r) if $\mu(r) \neq S$ and if r prefers S to $\mu(r)$ and S prefers r to σ for some σ in $\mu(S)$. (Note that σ may equal either some rushee r' in $\mu(S)$ or, if at least one of sorority S 's positions is unfilled at $\mu(S)$, σ may equal S .) Matchings blocked by an individual or by a pair of agents are unstable in the sense that there are agents with the incentive and the power to disrupt such matchings.

Definition: A matching μ is stable if it is not blocked by any individual agent or any sorority-rushee pair.

It is not obvious that this definition will be adequate, since we might need to consider coalitions consisting of sororities and several rushees (all of whom might be able to enroll at the sorority). However, it can be shown that considering larger coalitions would not change the set of stable outcomes, which equals the core of the game with respect to weak domination (see Roth, 1985b; Roth and Marilda Sotomayor, 1990).

Sets S of sororities and R of rushees, together with a vector P of preferences, one

for each agent, constitute a *matching market*.⁸ In what follows, we will assume for simplicity that all preferences over individuals are strict (i.e., that no sorority is indifferent between two acceptable rushees and no rushee is indifferent between two acceptable sororities). (We do not assume that sororities may not be indifferent between different groups of rushees.)

IV. Analysis of the Algorithm

We begin with a model of the market up to the conclusion of the PBS algorithm: in this part of the market, each sorority may admit q new members (q is the same for all sororities). We will refer to this as the market with quota q .

Some notation will help describe the working of the algorithm. Denote by $x'(r_i) = S_j$ that rushee r_i was matched to sorority S_j during step t , where a *step* is the working of the algorithm associated with a reading of a single rushee's preference card. Denote by $x'(r_i) = r_i$ that rushee r_i was assigned as unmatched during step t . At step t when a rushee r_i 's preference card is read, if r_i neither matches to a sorority nor is assigned as unmatched, then her preference card will be placed in "hold" and will be reread after all other rushees who have yet to be assigned (as unmatched or matched to a sorority) have had their preference cards read. Finally, denote by $x(r) = S$ that rushee r was matched to sorority S at some step of the algorithm, and similarly denote by $x(r) = r$ that rushee r was assigned to be unmatched; define $x(S)$ to be the set of all rushees assigned to S (i.e., $x(S) = \{r | x(r) = S\}$). Note that x is not a matching, because it is not defined for all rushees, but only for

those not left in hold when the algorithm ends, and because $|x(S)|$ may be less than q (the remaining positions are not filled with copies of S).

Sororities indicate preferences by listing rushees on a first bid list of no more than q names and a second bid list. Denote by $r_i \in Q_t(S_k)$ that rushee r_i is listed on the first bid list of sorority S_k at step t in the algorithm. That rushee r_j is listed on the second bid list of S_k at step t in the algorithm is denoted by $r_j \in Q_t^+(S_k)$. For each sorority, the bid list at step $t=0$ is the original bid list.

Consider next what the algorithm does when confronted with preferences for which it is well-defined (i.e., for which it does not fail to produce a matching).

THEOREM 1: *If no rushees are left in "hold" at the end of the PBS algorithm, its outcome is stable in the market with quota q .*

Theorem 1 is proved in the Appendix.

Furthermore, the PBS algorithm has the property that all its assignments are *inevitable*, in the sense that all rushees who match to sororities by the PBS algorithm must match to the same sorority at every stable outcome and rushees assigned as unmatched by the algorithm must be unmatched at every stable outcome in the market with quota q . That is, we have the following result (proved in the Appendix).

THEOREM 2: *The preferential-bidding-system algorithm only makes inevitable assignments in the market with quota q .*

An immediate consequence of the theorem is the following.

COROLLARY: *The preferential bidding system assigns all rushees only when there exists a unique stable outcome in the market with quota q .*⁹

⁸This matching market is an example of what is sometimes called a "college admissions" model (see David Gale and Lloyd Shapley, 1962). When quotas all equal 1, the model is symmetric between both sides of the market and is called the "marriage model." For many years, it was thought that the college admissions model was essentially equivalent to the marriage model. That this is not the case was shown in Roth (1985a). The model presented here is the college admissions model as reformulated in Roth (1985a).

⁹The converse is not true; it is possible to construct examples in which the algorithm fails to produce a matching even though there is a unique stable matching.

The corollary confronts us squarely with a puzzle. Typically there may be many stable outcomes to this kind of two-sided matching market, but the PBS algorithm is rarely observed to fail. To see how these two observations may be resolved, we will examine data from a number of rushes in Section V; but first consider the operation of the PBS algorithm as part of the larger market in which sororities may be able to admit more than q new members, even though they are not allowed to fill more than q positions through the algorithm. Specifically, consider a market in which the membership of each sorority S_k before formal rush is m_k , in which quota for the PBS algorithm is q , and in which the total allowable size for any sorority is T . Then, the number of positions sorority S_k may be able to fill either through formal rush or the informal rush which follows is $q_k = \max\{q, T - m_k\}$. That is, every sorority has the right to fill up to q positions (whether or not this will bring membership above T), and any sorority that has not filled q positions or does not have T members at the end of formal rush is able to continue recruiting new members. We have the following result.

THEOREM 3: *In the market with quotas q_k , matchings produced by the PBS algorithm with quota q may not be stable.*

PROOF:

Suppose the first $q + 1$ rushees on the bid list of some sorority S_k with $q_k > q$ all list S_k as their first choice. Further suppose that the $(q + 1)$ th rushee on S_k 's bid list, r_{q+1} , lists sorority S' as her second choice and that S' lists r_{q+1} among its first q rushees. Then, if the PBS algorithm with quota q results in a matching μ , Theorem 1 implies that $\mu(r_{q+1}) = S'$; but μ is unstable in the market with quotas q_k , since in that market S_k has a vacant position, and μ is blocked by (S_k, r_{q+1}) .

There is ample reason (both empirical and theoretical) to believe that instabilities give agents strong incentives to circumvent the procedures that produce them. Therefore, Theorem 3 raises a further question

about how the PBS algorithm has survived for so long. The empirical observations reported next will shed some light on this.

V. Some Empirical Observations

Preference cards and bid lists from formal rush were solicited from 12 campuses. These are regarded as highly confidential, and only four of the campuses agreed to make this material available, and then only under the condition that neither the names of sororities and rushees nor the campuses themselves would appear in any report. The data from 21 recent PBS-algorithm assignments taken from the four campuses are summarized in Tables 2, 3, and 4.¹⁰

Campus A is a rural college with approximately 1,500 full-time students; B is an urban university with a full-time undergraduate enrollment of about 4,500; C is a university in a rural setting with approximately 10,400 full-time undergraduates; and D is an urban university with roughly 9,400 full-time undergraduates. These four campuses are not a representative sample. All are located in the northeastern United States, and each had many sororities whose membership was sufficiently below their maximum capacity (their "total") so as to pose only loose constraints on the number of bids they could issue after formal rush.

As this latter factor will play a role in our subsequent analysis, the number of sororities that have "constrained" and "unconstrained" totals is noted below each table. Operationally, a sorority was said to be constrained only if the number of rushees on its second bid list who listed that sorority as their first choice was greater than the number of positions the sorority had available after formal rush (see Section VI). Other-

¹⁰In all but one case, the reported statistics are based upon the original preference lists (these were not available in 1986 on campus C: the statistics for that year were compiled by an administrator with direct access to the data). Some of the campuses retained old records and had many past PBS assignments available. Others only kept the most recent PBS assignments.

TABLE 2—CAMPUS A DATA

Statistic	1982 ^a	1983	Spring 1984	Fall 1984 ^a	1987
Number of rushees	93	84	72	92	68

Suicides (percentage)	50.5	45.2	68.1	58.7	69.1

Notes: The maximum chapter size (T) was 55. Of the five sororities on campus A, two were constrained and three were unconstrained. There were two periods of formal rush in 1984. In 1984, the timing of formal rush was changed from spring (1982–1984) to fall. The 1985 fall formal rush results were unavailable. In 1986, formal rush was again changed to the spring.

^aIn 1982, an error occurred in the execution of the PBS algorithm. In fall of 1984, quota was incorrectly determined to be 25 when it should have been 21.8 or 22. The numbers shown in parentheses are the correct statistics based upon the correct assignments. All statistical tests are based upon the statistics resulting from the actual (not the correct) assignments.

^bBoth rushees who listed three choices matched to their first choice. Note that neither rushee was listed by her second- or third-choice sorority.

wise, the sorority was said to be unconstrained. With one exception, the constrained status of each sorority has remained unchanged over the years under observation.¹¹

The most striking feature of the data is the high percentage of rushees who chose to

list only one sorority on their preference card. This is particularly striking in view of the fact that this practice ("suiciding") is explicitly discouraged.¹² Nevertheless, of the

¹¹In the most recent PBS assignment occurring on campus D (1987), some sororities became constrained (see notes to Table 4).

¹²The following suggestions or guidelines were listed in an orientation booklet distributed to rushees during formal rush on one of the campuses we studied:

...if a rushee does not receive her first choice, she must be willing to accept any of the other choices she has listed. However, if she only preferences one sorority (sometimes called

Notes: The maximum chapter size (T) was 50. Of the six sororities on campus B, two were constrained and four were unconstrained. This campus had two formal rush periods every year, fall and spring, until 1982. The 1982 data represent the first year that there was only one formal rush period, held in the spring. Formal rush has continued to be held in the spring since 1982. There are two missing observations: spring 1980 and fall 1981. In 1986, an error occurred in the execution of the PBS algorithm. This error had no effect upon the aggregated statistics.

21 rushes observed on four campuses, there were only three in which the number of rushees suiciding was less than 50 percent of those who submitted preference cards. Even on campuses C and D, which each have a dozen or more sororities active in formal rush, relatively few rushees list more

than two sororities on their preference cards.

In Tables 2–4, the number of “suicides” is given immediately below the number of rushees submitting preference cards (with the percentage given in the last line of the table). For comparison, the number of rushees listing two choices on their preference lists and the number with three choices are also given. For each of these, the table shows how many were matched by the algorithm, broken down into how many are matched to their first, second, and third choices. Also shown for each category of rushees is the number of times a rushee

“suiciding”) she must realize she is limiting her chances of pledging a sorority all together.

No sorority shall encourage a rushee to single preference their sorority (suicide).

Notes: The maximum chapter size (*T*) was 65 on campus C and 55 on campus D. All of the 13 sororities on campus C and all of the 12 sororities on campus D were unconstrained during 1984–1986; in 1987, three of the sororities on campus D were constrained, and nine were unconstrained. Campus C requires that a sorority list all rushees who were extended a bid to its final party somewhere on its bid list. All rushes for both campus C and D take place in the fall. Quota-plus was adopted during the 1984 formal rush on Campus D, quota-only was adopted for all other years (1985–1987). On Campus D, sorority totals became relevant for the first time in 1987. The PBS algorithm failed to assign all rushees in 1987.

^aAn error occurred in the execution of the PBS algorithm on Campus D in 1986. The numbers shown in parentheses are the correct statistics based upon the correct assignments. All statistical tests are based upon the statistics resulting from the actual (not the correct) assignments.

placed on her preference card a sorority that did not in turn list the rushee, either on the first or second bid list.

For example, Table 3 shows that, in the 1979 rush on campus B, 62 rushees signed preference cards. Of these, there were 53 rushees who listed only a single sorority, and 52 of these were matched to that sorority, while one was unmatched. In this case, we can see that this is because one rushee

who listed only one sorority was not listed on that sorority's bid list. Similarly, nine rushees listed two sororities, and all nine were matched to their first choice. One of the sororities so listed did not place one of these rushees on either of its bid lists. Over 98 percent of the rushees were matched (all to the first choice on their preference cards), in a rush in which over 85 percent listed only one sorority on their preference card.

TABLE 5—DATA ON CONTINUOUS OPEN BIDDING

Campus	Year	Number of rushees unmatched during formal rush		Number of rushees matched to first choice during continuous open bidding	
		Suicides	Nonsuicides	Suicides	Nonsuicides
C	1985	5	0	1	0
C	1986	14	0	1	0
D	1984	12	5	11	4
D	1985	16	0	14	0
D	1986	13	2	13	2
D	1987	3 (9)	2 (5)	2 (4)	2 (3)

Notes: The 1984 data on campus C were unavailable. The 1987 results for campus D are broken into two groups, depending on whether the first-choice sorority was constrained or unconstrained. The first number is the number of rushees whose first choice was unconstrained, while the number in parentheses is the total number of rushees (i.e., those whose first choice was constrained plus those whose first choice was unconstrained). For example, nine rushees listed only a single sorority, of which three listed an unconstrained sorority. Of these three, two matched to their first choice in continuous open bidding.

On this campus, the maximum membership allowed in a sorority (T), which is the same for each sorority on campus, is 50, and of the six sororities on campus, only two were near enough this number so that it could constrain their post-PBS bidding.

The maximum number of rushees each sorority can be assigned under the PBS algorithm (quota) will vary each year. Quota is the number of rushees attending the first round of invitational parties divided by the number of sororities on the campus. Quota is not shown in the tables nor can it be calculated from the information given. The "number of rushees" shown in the tables is the number signing preference cards, which may be substantially smaller than the number of rushees attending the first round of preference parties.

The PBS algorithm failed to assign all rushees (as either matched to a sorority or as unmatched) on campus D during the 1987 formal rush. This was the only failure observed. Those rushees not assigned by the PBS algorithm were assigned by the individual in charge of the execution of the PBS algorithm. (The resulting matching was stable; see Mongell [1988] for an analysis of this incident.) The statistics in Tables 2–4 indicate the assignments made by the PBS algorithm. The quota-only method was

adopted by all the campuses observed, except for one year (1984) on campus D. Under quota-only, sororities may extend additional bids to rushees assigned as unmatched by the PBS algorithm. The procedure by which these additional bids are extended varies on each campus (and sometimes from year to year). The sorority may be notified that an unmatched rushee's name appears on its bid list and asked whether it would like to extend her a bid. The sororities may be notified before the PBS execution that unmatched rushees whose names appear on their bid list will be extended bids (on the sorority's behalf) if the sorority has not reached quota during the PBS algorithm. From the available data it was observed that few sororities extended bids at this time. On some campuses, a rushee assigned as unmatched by the PBS algorithm will be called by one of the individuals involved with the PBS execution and asked whether she would be willing to join another sorority that listed her on its bid list and has not reached quota. It appears from the (limited) available evidence on this point that virtually all rushees so called have refused these bids.

The numbers of rushees assigned as unmatched by the PBS algorithm who match to their first choice during continuous open

bidding were available on campuses C and D and are shown in Table 5.

VI. Strategic Analysis

The data raise two questions. What accounts for the consistently high percentage of rushees who list only a single sorority on their preference cards? And how might this high percentage be related to the low frequency of failure of the PBS algorithm and to its long life? To address these questions requires a model of the entire rush process.

During the PBS algorithm, each sorority may gain up to q new members. Following the PBS algorithm, there is a second stage of formal rush during which one additional set of bids and acceptances or rejections may be made (with how many bids depending on whether the quota-only or quota-plus rules are adopted). Finally, following formal rush there is continuous open bidding, during which each sorority with fewer than T members (both new members and old members who have not yet graduated) may admit new members to bring its membership up to T (and each sorority that has not yet enrolled q new members may bring its new members up to q). On the campuses from which our data are drawn, T imposed such a loose constraint that most sororities could attempt to recruit all rushees who showed serious interest in them. (These are the "unconstrained" sororities noted below in Tables 2–4.) That is, on these campuses, the demand for membership in most sororities is less than the supply, in the sense formalized by the following definition.

Definition: A sorority S is unconstrained if its membership is sufficiently below its allowed total so that it can extend bids to all rushees who it finds acceptable and who have S as their first choice among all sororities that find them acceptable.

Nevertheless, the number of rushees interested in joining even an unconstrained sorority may exceed q . As we saw in the proof of Theorem 3, a rushee who lists more than one sorority on her preference card runs the risk of being matched to her

second-choice sorority during the PBS algorithm and forgoing a chance to be matched to her first-choice sorority after the formal rush. For simplicity, consider the case in which all sororities have unconstrained totals (i.e., for every sorority S_k , the number of acceptable rushees who regard S_k as their first choice is less than q_k , where $q_k = \max\{q, T - m_k\}$ is the number of positions S_k may fill by the end of open bidding).

We model the matching procedure as a multistage game. In stage 1, all sororities and rushees simultaneously state preferences and are matched by the PBS algorithm. In stage 2, the unmatched rushees are announced, as are the sororities that have not filled q positions (if the quota-only rules are used, or which have fewer than T members, if the quota-plus rules are used). Each such sorority S_k may issue invitations to up to $q - |x(S_k)|$ (or $q_k - |x(S_k)|$) unmatched rushees, and each rushee who receives invitations may accept at most one. In stage 3 and subsequent stages, all matches from previous stages become public, and any sorority S_k that has been matched to a set $y(S_k)$ of rushees in the prior stages may issue invitations to up to $q_k - |y(S_k)|$ rushees who have not been matched to sororities in earlier stages. Each rushee may accept at most one invitation and must decline all others when they are received; at any stage in which she accepts an invitation, she is matched. Starting with stage 4, no sorority may issue an invitation to a rushee to whom it has previously issued an invitation at stage 3 or later. The game ends at any stage in which no invitations are issued. Stages 1 and 2 represent formal rush, with stage 1 corresponding to the PBS algorithm and stage 2 corresponding to the quota-only (or quota-plus) system. Subsequent stages represent open bidding.

Note that we have chosen one of several possible ways to model the second stage of formal rush. Also, by dividing the bidding into stages we have imposed on the model some structure beyond what we observe in practice in open bidding. Finally, so the game will end in finitely many periods, we have imposed the rules that sororities may

not reinvoke rushees and that rushees must either accept or reject all invitations in the period they are received. These choices seem to be among the simplest that are broadly consistent with the sometimes diverse and sometimes ambiguous rules of the rush process. Because there is some irreducible arbitrariness in choosing the elements of a model, it is also important to note that the equilibrium considered below seems robust to changes in these arbitrary features of the model.

We would like to demonstrate that the observed behavior corresponds to equilibrium behavior in this market. One potential difficulty we face is that we have not fully specified what happens when the PBS algorithm fails. To show that a particular set of strategies is in equilibrium, we have to show that no agent can profitably deviate, and for this we have to show that no agent can profitably deviate even in a way that causes the algorithm to fail. As noted earlier, different individuals charged with supervising sorority rush have indicated that they would proceed differently in the circumstances we call failure (i.e., in these circumstances, the results would be different on different campuses). One approach, therefore, would be to make further assumptions about how the algorithm would proceed on each of these campuses. We take a different approach and demonstrate an equilibrium with the properties that only rushees can deviate in a way that might cause the algorithm to fail and no rushee can profit from this, no matter how failures are resolved (however failures of the PBS algorithm might be resolved on different campuses, rushees may not be matched to sororities that have not issued them invitations).

THEOREM 4: *Suppose all sororities are unconstrained. Then:*

(a) *The following strategies constitute an equilibrium in the multistage game. In the first stage, each rushee lists only her first-choice acceptable sorority (from among those that find her acceptable) and in subsequent stages accepts only an offer from this sorority. Each sorority S_k lists its true preferences in the first stage and makes offers in stage 2 to*

its most preferred $q_k - |x(S_k)|$ acceptable rushees from among those unmatched in stage 1. In stage 3, it makes offers to all of its $(q_k - |y(S_k)|)$ highest-ranked unmatched rushees, and in any subsequent stage it makes offers to its highest-ranked set of unmatched rushees who have not previously rejected it.

(b) *Furthermore, at this equilibrium the PBS algorithm never fails, and the matching that results is stable in the market with quotas q_k (it is the rushee-optimal stable matching).*

PROOF:

We prove part b first. Suppose the rushees and sororities play the strategies described. To see that the PBS algorithm does not fail, suppose to the contrary that it ends with some rushee r_i in hold. Then r_i must be on the second bid list of the sorority on the top of her preferences at the final step of the algorithm, and this sorority, S , must not have reached quota (since if it had it would have been crossed off r_i 's preference list at box D of the flow chart in Fig. 1). Therefore, there must be another rushee, r_j , not matched to S but in the first q positions of S 's final bid list. However, this cannot be, since r_j has listed only one sorority. If this is not S , then r_j would have been crossed off S 's list at box B of the flow chart, and if it is S , then (all such) r_j would be matched to S , contradicting that S has not reached quota. Therefore, the PBS algorithm leaves no rushees in hold; that is, it does not fail.

When all agents play these strategies, each rushee is eventually matched to her first choice among all acceptable sororities that find her acceptable. Since this matching is individually rational and not blocked by any sorority-rushee pair, it is stable, and since each rushee is matched to her highest-ranked achievable match, it is the rushee-optimal stable matching μ_R . This completes the proof of part b.

To prove part a, we show that no sorority or rushee can do better than to play the strategy described, so long as the other agents all do so. First consider sororities. As we saw in the proof of part b, so long as all rushees list only a single sorority on their preference cards, the algorithm will not fail, regardless of what sororities may do. Fur-

thermore, if the rushees follow the strategies indicated in the theorem, any sorority S that deviates from the strategy indicated for it will be matched to a subset of $\mu_R(S)$, rather than to all of $\mu_R(S)$. Since S has responsive preferences over groups of rushees, and since all rushees in $\mu_R(S)$ are strictly preferred to vacant positions, S prefers $\mu_R(S)$ to any strict subset of $\mu_R(S)$, and so cannot profit from any such deviation.

Now consider rushees. For each r , $\mu_R(r)$ is r 's most-preferred mutually acceptable sorority; that is, $\mu_R(r)$ is the most preferred match r can achieve at any individually rational outcome (if there are no mutually acceptable sororities, $\mu_R(r) = r$.) Therefore, if r deviates from her indicated strategy, she cannot improve her outcome even if by deviating she causes the PBS algorithm to fail, since no rushee may be matched to a sorority that has not issued her an invitation.

While the equilibrium specified in Theorem 4 is not a perfect equilibrium, the equilibrium behavior is certainly consistent with perfectness. Since the extensive-form game begins with the simultaneous submission of all parties' preferences, all equilibria are subgame perfect. However, after formal rush, all parties learn all the payoff-relevant information of the game, and the subsequent information sets all consist of single nodes, so an appropriate formulation of perfectness is backward induction to the nodes of stage 3. The off-the-equilibrium-path behavior we must consider arises if a rushee's first-choice sorority fills all its positions before issuing her an invitation. In this event, the rushee's strategy should be, from stage 3 onward, to accept the offer from her highest-ranked sorority among those that will still have positions to offer when they reach her, following the strategy for sororities given in the theorem.¹³ Note also that

the stage-2 behavior of sororities plays little role in this equilibrium (e.g., nothing would change if sororities made no offers in stage 2 but otherwise behaved as in Theorem 4).

Theorem 4 considers the case in which all sororities are unconstrained, whereas in our data this was the case only on campuses C and D; both campuses A and B had some constrained sororities, although most were unconstrained. Thus, the assumptions of the theorem do not precisely model the situation we observed any more than the equilibrium strategies it characterizes precisely mirror the data, which on every campus show significant numbers of rushees listing more than a single sorority on their preference cards in almost every year. Similarly, the equilibrium outcome has all rushees ultimately matched to the sorority they list first on their preference card, while Table 5 shows that, of campuses C and D, this approximately characterizes only the situation on campus D. However the theorem shows how the striking regularities observed in our data can arise at equilibrium. It shows how stage 2 of the formal rush procedure plays a much less important role than does the continuous open bidding which follows formal rush. Most importantly, it makes clear why the presence of unconstrained sororities may be expected to give so many rushees an incentive to list only a single sorority. Even when some sororities have tighter constraints, this incentive persists, since for example a rushee whose first-choice sorority is constrained but whose second-choice sorority is unconstrained also has no incentive to list more than her first choice when the strategies are as described.

Theorem 4 and its proof also suggest why an increase in the number of rushees who list only one choice on their preference cards will reduce the probability that the PBS

¹³If the constraints on sororities were completely relaxed (e.g., if the quotas q_k all exceeded the number of rushees), then the equilibrium in Theorem 4 would be perfect, and μ_R would be the unique stable match-

ing. However such a relaxed constraint does not describe what we observed. Similarly, we could have modeled open bidding by rules that would lead to stable outcomes at every perfect equilibrium regardless of the quotas (see Roth, 1984b; Roth and Sotomayor, 1990), but this would involve imposing particular detailed rules beyond what we observe.

algorithm will fail, even if some rushees behave differently. That is, increasing the number of rushees who submit a single choice on their preference cards may remove the cause of failure of the PBS algorithm but may never cause failure. The following proposition, stated without proof, formalizes this.

PROPOSITION: *Let P be a collection of stated preferences for a set S of sororities and a set R of rushees, and let P' be a collection that differs from P only in that some of the preference orderings in P have been truncated after their first element. Then the PBS algorithm with input P' will never fail if the PBS algorithm with input P does not.*

VII. Modeling Issues and Open Questions

Many choices must be made in modeling a complex system. We have already pointed out some of the modeling decisions we have made. Here, we discuss some aspects of sorority rush that we have not included in the formal analysis. Our motivation for discussing these explicitly is that, if such choices are not made carefully, the conclusions of the analysis may be misleading. Therefore, we want to explain briefly the reasons behind our choices. Then, we turn to some open questions.

First, although we have modeled sororities as being concerned with groups of rushees, we have modeled rushees as having preferences only over sororities and not over which other rushees join the same sorority. This seems justified both because particular sororities typically draw from the same part of the rushee population year after year (so preferences over sororities are a good proxy for preferences over other rushees) and because rushees are typically freshmen who have not yet had time to form many close friendships with other freshmen. Nevertheless, it is not unheard of for pairs of rushees, typically friends from high school, to wish to join the same sorority, and the problem facing such a pair differs from that analyzed here.

Second, our strategic analysis considered only the behavior of individual rushees and

sororities and not sorority-rushee coalitions. There may be an additional reason why some rushees list only a single sorority, since in some circumstances it may be in the interest of an unconstrained sorority to encourage certain rushees to do so, although this is regarded as one of the more serious violations of the rules. Briefly, certain rushees (called "legacies") may have close relations with a given sorority even before the beginning of rush, by virtue of having a family member who is a member or alumna of that sorority. If this rushee r lists only that sorority S on her preference card, then sorority S can plan to list rushee r somewhere on its second bid list, and can count on enrolling her during open bidding. This permits the sorority to rank higher on its bid list other rushees, who may list more than one sorority and who might therefore be matched during the PBS algorithm to another sorority if sorority S submitted its true preferences. We have been unable to gather data on how widespread this phenomenon might be, both because it is explicitly forbidden by the authorities concerned with rush and because it is not easily distinguishable from the simpler reasons for listing only a single sorority already described.¹⁴ That is, the reasons this might be a viable agreement between a sorority and a rushee are not substantially different from the reasons that individual rushees, acting on their own, might choose to submit a single preference.

Third, we have not analyzed the several rounds of parties described in Section II, which precede the submission of preferences by sororities and rushees. Our sense is that, on the campuses we have observed, because most sororities are unconstrained or only loosely constrained, the strategic considerations that arise in deciding which rushees to invite and which parties to accept have at most secondary importance, and the primary role of the parties on these

¹⁴We are indebted to Patty Beeson for pointing out to us that some sororities have rules that any legacy who attends the final preference party must be listed on the first bid list.

campuses is to help rushees and sororities form their preferences and signal them to one another.

This brings us naturally to the next modeling issue. We have analyzed the game as a game of complete information, in which sororities and rushees know one another's preferences. Essentially we are assuming that, in the course of the preference parties, these preferences are fully communicated. This is obviously only an approximation of reality, but a rough idea of how adequate this approximation might be can be gotten from Tables 2-4, which show how many times a sorority was listed on the preference card of a rushee who did not appear anywhere on its bid list. Each such incident is likely to be a case in which the complete-information assumption is not met.¹⁵ The relatively low frequency of this suggests that the complete-information assumption is a rough approximation of what we observed. Note that, while the assumption of complete information is certainly less than fully satisfactory, serious new problems would arise in attempting to model the game as one of incomplete information, since the results of such an analysis would be sensitive to the assumptions that would have to be made about participants' prior probability distributions.¹⁶

Finally, our analysis has treated each sorority as an individual agent and not as a collection of individual members. Given that each sorority is required to submit a single

bid list, this may not raise problems, but we note that we have not investigated any aspect of how sororities arrive at their bid lists. In this regard, Roth and Sotomayor (1989) show there is a surprising coincidence of preferences over stable matchings among agents with different responsive preferences over groups, provided they have the same preference over individuals. Thus, for many purposes, the relevant differences among sorority members will be precisely those that go into determining the preferences over individuals (i.e., the bid list) and not more complex issues regarding the makeup of the entire entering group of new members.

We now consider briefly one of the major open empirical questions raised by this work: on campuses having mostly constrained sororities, how will rush differ from what we have observed on campuses with mostly unconstrained sororities? We conjecture that there will be at least two important (and related) differences. As we have seen, the high percentage of rushees listing only one sorority on their preference cards in formal rush is related to the fact that this (unconstrained) sorority can issue further invitations during open bidding.¹⁷ This will not be so on campuses in which most sororities cannot accept new members after the end of formal rush, and so on these campuses we expect to see a very much smaller percentage of single preferences.

This brings us to the second major difference we expect. Recall that the PBS algorithm as delineated in the literature of the National Panhellenic Council is incompletely specified: for some configurations of preferences, it does not indicate how some rushees should be dealt with. As we saw, the very low frequency of this kind of failure in our data can be attributed to the high percentage of rushees who submit single preferences. If the percentage of single preferences is much lower on campuses with

¹⁵Of the four campuses observed, only the sororities on campus C are required by their college panhellenic to list every rushee invited to the final preference party somewhere on their bid list. Thus, the invitations to the final round of parties are particularly effective signals of sorority preferences on campus C (but even on this campus, there was one case of an unlisted rushee in 1986; see Table 4).

¹⁶Although perhaps some headway could be made due to the fact that the preferences of rushees for sororities and those of sororities for rushees may follow certain identifiable patterns (e.g., on a given campus some sororities may be known as athletic, others as wealthy, etc.). A discussion of equilibria when agents have incomplete information about other agents' preferences is found in Roth (1989) and Roth and Sotomayor (1990).

¹⁷At least in theory. The differences between the various campuses in our data set (see the notes in Tables 2-4) preclude meaningful statistical comparisons across campuses (see Mongell, 1988).

constrained sororities, it seems likely that the frequency of failure (i.e., the percentage of rushes in which the submitted preferences fall outside of those that can be fully processed by the standard instructions for the PBS algorithm) will be higher. (Indeed, the one failure that occurred in our data was on campus D in 1987, the first year some of the sororities on that campus became constrained.) This suggests that supplementary rules will be adopted on these campuses to determine what the algorithm should do in such cases. Since it appears that these rules will have to be developed separately on each campus, there may be more variation in the formal rush procedures found on such campuses (as well as in the strategic behavior of rushees and sororities).

Finally, on campuses with many constrained sororities, it seems likely that the initial rounds of preference parties would involve nontrivial strategic decisions. (For example, if you can only accept two final invitations, it might sometimes be advisable to decline an invitation from your first-choice sorority, in order to signal your interest to a lower-ranked choice which has a greater chance of giving you a high ranking on its preference list.) As described in Section II, a good deal of formal structure is involved in these parties, much of which is common from campus to campus, which would help in modeling the strategic aspects of these decisions.¹⁸

A second kind of open question is: what caused the unraveling of recruitment dates that occurred in this market prior to the introduction of the PBS, and what caused this unraveling to stop? Sorority rush may not be the two-sided matching market that will best illuminate these issues,¹⁹ but be-

cause this phenomenon occurs in other two-sided matching markets, the unraveling observed in sorority rush appears to be an example of a much more general phenomenon (see Roth 1984a, 1991).

VIII. Conclusions

One way to summarize this story is to say it is about the difficulty of central planning. The agreement hammered out in the 1920's among sororities to reduce the competitiveness of recruitment implemented a plan designed to give all sororities the ability to recruit the same number q of new members, before any sorority had a chance to recruit more. When sororities have capacity greater than q , which is the case on the campuses we have observed, this could in general lead to unstable outcomes (Theorem 3). That is, there will in general be rushees and sororities who share an incentive to circumvent this constraint. As we have seen, the agents in the market have adapted their behavior to do so: rushees list only their first-choice sororities in the part of the procedure constrained by the quota q , and sororities approach desirable rushees after this constraint has been lifted. Ironically, this adaptation contributes to the smooth operation of what would otherwise be an incompletely specified procedure (Theorem 4).

From a more general perspective, this study reaffirms the importance of examining systems of rules from the point of view of what incentives they give participants. If we had looked only at the formal rules of the PBS algorithm and analyzed it as if agents all submitted their true preferences, we would not have been able to explain what we were seeing. However, the data on submitted preferences clearly made it unlikely that rushees were submitting their true full

¹⁸For example, of the campuses we observed, all but campus B permit each rushee to attend only two final parties during the last round of the invitational parties. (Campus B permits rushees to attend up to three final preference parties.)

¹⁹Since sororities are subject to some sanctions (both from the national organization and from campus authorities), they may be able to enforce an agreement on

recruiting behavior simply, once it has been reached. Also, with the increased mobility of college students, there may not be much room to unravel recruiting much before the beginning of the freshman year (i.e., the unraveling may have stopped only because it has no further to go).

preferences, and the subsequent analysis of their incentives suggested that they were responding rationally to the incentives of the system.

We reemphasize that we study sororities not merely because of their intrinsic interest, nor merely to show that game-theoretic analysis can shed light on behavior that might not always be thought of as economic. The point of studying particular matching mechanisms is that they add to our understanding of how centralized matching mechanisms work in general (and there seems to be a surprising number of these). By understanding how centralized mechanisms work in practice, we can also hope to learn things that will be useful in the study of decentralized two-sided matching markets (see Roth and John H. Vande Vate, 1990, 1991). The advantage of beginning with centralized markets is that it is easier to determine when they reach stable outcomes and when they do not. The theoretical progress in studying labor and other markets as two-sided matching models (see references in Roth and Sotomayor [1990]) suggests that this kind of empirical research may be fruitful. The conclusions of the present study should lend further weight to the hypothesis that the stability or instability of the matchings that result from such a market are crucial to understanding the market's evolution.

If game theory is to become as important a part of empirical economics as it has become a part of economic theory, we must explore the kinds of empirical research that will allow us to test and refine game theory. Since game theory is the part of economic theory most particularly concerned with the "rules of the game," this will inevitably involve looking into the particular rules by which markets are organized. At the same time, as was emphasized in Roth (1991), notions like the stability of outcomes, which can be formulated somewhat independently of the particular rules of the game, are useful in comparing different sets of rules and in indicating when agents may have an incentive to change the rules or circumvent them.

APPENDIX

The following results from the literature will be of use.²⁰

THEOREM A1: *A stable matching exists for every matching market.*

Definition: For a given matching market (S, R, P) , a stable matching μ is S-optimal if every sorority likes it at least as well as any other stable matching. Similarly, a stable matching ν is R-optimal if every rushee likes it at least as well as any other stable matching.

Definition: A sorority S and a rushee r are achievable for each other in a matching market (S, R, P) if S and r are paired at some stable matching.

In a matching market in which all rushees and sororities have strict preferences over individuals and in which sororities have responsive preferences over groups, each sorority and rushee can strictly order its or her achievable mates, and so there can be at most one S-optimal stable matching and one R-optimal stable matching.

THEOREM A2: *When all sororities have strict preferences over individual rushees and all rushees have strict preferences over sororities, there always exists an S-optimal stable matching, μ_S , and an R-optimal stable matching, μ_R .*

THEOREM A3: *When all agents have strict preferences, the S-optimal stable matching is the worst stable matching for all the rushees; similarly, the R-optimal stable matching is the worst for all the sororities.*

²⁰Theorems A1 and A2 were proved in Gale and Shapley (1962), and Theorem A3 was proved in Donald Knuth (1976) for the marriage model. They hold not only for the marriage model, but also for the college admissions model considered here (see Roth and Sotomayor, 1990). Theorem A4 is from Roth (1984a); for a stronger result motivated by the American medical labor market, see Roth (1986).

We will also use the following result.

THEOREM A4: *When all preferences over individuals are strict, the set of rushees matched to sororities, and sorority positions filled, is the same at every stable matching.*

Theorem 1 follows immediately from the following proposition, which will also be useful in the proof of the next theorem.

PROPOSITION 1: *If r_i is not in hold when the algorithm stops, then any sorority S_k that r_i prefers to $x(r_i)$ does not prefer r_i to any element of $x(S_k)$.*

PROOF:

Consider a rushee r_i who is not in hold when the algorithm stops. Let t be the step at which this rushee is given an assignment (i.e., either matched to a sorority or left unmatched). Then $x'(r_i) = S_i$ for some sorority S_i , or $x'(r_i) = r_i$. In the former case (box A in Fig. 1), S_i is at the head of rushee r_i 's preference card at step t . (Note that such an assignment must be individually rational for both r_i and S_i .) In the latter case (box E or F), either the rushee's current preference card is empty (box F) or it contains only a sorority S_j that did not list rushee r_i (box E).

There are two points in the algorithm at which a sorority S_k can be deleted from the rushee r_i 's preference card: these are boxes C and D in Figure 1. If the deletion occurs at box C, the sorority has not listed rushee r_i on its bid list and so does not prefer rushee r_i to any element of $x(S_k)$. If the deletion occurs at box D, then the sorority has filled its quota by matching to q rushees at the top of its bid list during some step $k < t$. Since rushees are deleted from the bid lists of sororities only at boxes A and B, rushee r_i has not been deleted from sorority S_k 's bid list prior to step k , so S_k prefers all the rushees in $x(S_k)$ to r_i .

The next proposition states that, even when the PBS algorithm fails to assign all rushees, the resulting partial matching could be extended to a stable matching in the market with quota q .

PROPOSITION 2: *There exists a stable matching μ in the market with quota q such that $\mu(r) = z(r)$ for every rushee r who is matched by the PBS algorithm.*

PROOF:

Consider the "residual matching market" which arises in the market with quota q after the PBS algorithm has ended in failure, with some rushees left in hold. Define the agents in this market to consist of those rushees left in hold, together with the set of sororities. The preferences of the sororities are as in their bid lists in the original market, except that all rushees who have been matched by the PBS algorithm are deleted. The residual quota of a sorority S_k in the residual market is given by $q'_k \equiv q - |x(S_k)|$. That is, in the residual matching problem we have just defined, each sorority may fill no more positions than were left unfilled by the PBS algorithm. (The preferences of the rushees in this residual matching problem can be thought of either as the same as given by their preference cards in the original problem or as having deleted those sororities that now have a quota of 0.)

Let x' be a stable matching for the residual matching problem. Let μ be the matching for the original matching problem with quota q , such that for each rushee matched by the PBS algorithm, $\mu(r) = x(r)$ and for each rushee left in hold, $\mu(r) = x'(r)$. We will show that μ is stable in the market with quota q .

Suppose not. Then, since μ is individually rational, there is a sorority rushee pair (S, r) such that r prefers S to $\mu(r)$, and S prefers r to some σ in $\mu(S)$. It cannot be that r was assigned by the PBS algorithm, since if that were the case we would have $\mu(r) = x(r)$, which implies that, at the step of the algorithm at which r was matched to $x(r)$, sorority S had already filled its quota, so $\mu(S) = x(S)$, and by Proposition 1, (S, r) is not a blocking pair. Therefore, r was left in hold at the end of the PBS algorithm. Then, σ cannot be equal either to S (an unmatched position) or to a rushee r' in the residual matching problem, since this would contradict the stability of x' in that market. Therefore, σ must equal some rushee r'

with $x(r') = S$. Note that r cannot have listed only one sorority on her preference card, and so the fact that r' was matched to S while r was still unmatched implies $|x(S)| < q$ (since rushees can be deleted from sorority bid lists only at points A and B in the flow chart in Fig. 1). Therefore, r is one of the q' highest rushees in S 's preferences in the residual market. Thus, x' cannot be stable in the residual market, which is the contradiction needed to conclude that no blocking pair (S, r) exists, and so μ must be stable.

LEMMA: *If S_k is r_i 's most preferred achievable match and r_i is among S_k 's q most preferred achievable matches, then (r_i, S_k) is an inevitable match in the market with quota q .*

PROOF:

Theorem A3 implies that S_k is both the best and the worst achievable sorority for r_i . Since preferences are strict, it is the only achievable match.

PROOF OF THEOREM 2:

The proof is by induction. Bear in mind that, by Proposition 2, if r_j is matched to S_p at some step of the algorithm, r_j and S_p are achievable for one another.

If, when $t = 1$, $r_i \in Q_1(S_i)$ and if, of the sororities that listed r_i , S_j is the highest-ranked sorority on r_i 's preference card, then $x^1(r_i) = S_j$, and this first match is inevitable. (In what follows, the ranking on the rushee's preference card refers to the original ranking when $t = 0$.) Thus, if a match is made at $t = 1$, it is inevitable. Now suppose that all matches up to time $t = k$ are inevitable; it will be shown that any match made at $t = k + 1$ is inevitable.

Consider the following cases:

(i) No match occurs at step $k + 1$.

Then all matches up to step $k + 1$ are inevitable by the inductive assumption.

(ii) A match $x^{k+1}(r_j) = S_p$ occurs at step $k + 1$ (i.e., rushee r_j is matched to sorority S_p at that step).

Then it must be that $r_j \in Q_{k+1}(S_p)$ and that, of the sororities that listed r_j and have not reached quota, S_p is the highest-ranked sorority on r_j 's preference card. First suppose that S_p is the highest-ranked sorority on r_j 's (original) preference card. Then the fact that $x^{k+1}(r_j) = S_p$ implies that S_p has not reached quota prior to step $k + 1$. (a) If $r_j \in Q_0(S_p)$, then (r_j, S_p) is inevitable (by the Lemma). (b) If $r_j \notin Q_0(S_p)$ but $r_j \in Q_0^+(S_p)$, then there exist other rushees that S_p prefers to r_j . Since $r_j \in Q_{k+1}(S_p)$, this implies that all of these rushees have either suicided or matched elsewhere (since rushees are deleted from sorority bid lists only at boxes A and B of the PBS-algorithm flow chart in Fig. 1). Any rushee who suicided cannot be matched to S_p at any individually rational outcome. Any rushee who was matched to some sorority other than S_p prior to step $k + 1$ is matched to that sorority at any stable outcome, by the inductive assumption. Therefore, none of these rushees can be matched to S_p at any stable outcome, and (r_j, S_p) is inevitable, by the Lemma.

Now suppose S_p is not the highest-ranked sorority on r_j 's (original) preference card of those that listed her somewhere on their bid lists. Let S_n be a sorority that listed r_j and was ranked before S_p on her preference card. Then the fact that $x^{k+1}(r_j) = S_p$ implies that S_n has reached quota at some step $t < k + 1$ (since sororities are deleted from rushee bid lists only at boxes C and D of the flow chart in Fig. 1). By the inductive hypothesis, S_n is not achievable for rushee r_j . Therefore, by the Lemma, r_j and S_p are inevitable.

(iii) A match $x^{k+1}(r_j) = r_j$ occurs at step $k + 1$ (i.e., rushee r_j is assigned to be unmatched at that step).

Proposition 2 and Theorem A4 together imply in this case that $\mu(r) = r$ at every stable matching.

Model Uncertainty, Learning, and the Gains from Coordination

By ATISH R. GHOSH AND PAUL R. MASSON*

This paper considers gains from international economic policy coordination when there is uncertainty concerning the functioning of the world economy but also learning about the "true" model on the part of policymakers. The paper reports estimates of plausible alternative versions of a standard two-country model. Activist policy (either coordinated or uncoordinated) may produce large welfare losses in the absence of learning, if policymakers believe in the wrong model; hence, exogenous money targets and freely flexible exchange rates may be best. However, model learning (from observations on macroeconomic variables) causes coordinated policies to dominate activist uncoordinated policies or exogenous money targets. (JEL F33, F42)

In recent years, there has been a marked increase in interest in international economic policy coordination, as evidenced by the proliferation of academic publications and of meetings of officials. Though the presumption is that policy coordination among the major industrial countries is a good thing, there exist valid doubts concerning the possibility of designing appropriate intervention and coordination rules when the effects of policies are uncertain. Speaking at the American Economic Association meetings in December 1987, Martin Feldstein noted, "Uncertainties about the actual state of the international economy and uncertainties about the effects of one country's policies on the economies of other countries make it impossible to be confident that coordinated policy shifts would actually be beneficial" (Feldstein, 1988 p. 10). Though coordinated policies may, *ex post*, turn out to have been ill-advised, the relevant question is whether they are likely to result in

higher welfare on average than uncoordinated policies, despite the presence of such uncertainties.

The issue has been discussed in several recent papers, though a consensus on the implications of model uncertainty for the desirability of coordination has yet to be achieved. Jeffrey Frankel and Katharine Rockett (1988) argue that model uncertainty makes coordination too risky and that, on average, countries are as well off pursuing noncooperative policies as they are under coordination.¹ In contrast, we have argued in another paper that the existence of model uncertainty does not necessarily preclude a beneficial role for the coordination of macroeconomic policies; indeed, it may in fact provide an additional incentive to coordinate policies internationally (Ghosh and Masson, 1988; see also Ghosh and Swati Ghosh [1991]). The reason for this is that, in the choice of optimal policies, coordination will properly take into account the effects of those policies on global economic uncertainty.

The differences in conclusions stem from two essential differences in approach. First

*Department of Economics, Princeton University, Princeton, NJ 08544 and International Monetary Fund, Washington, DC 20431. We are grateful to Mike Dooley, Dale Henderson, and an anonymous referee for helpful comments. The views expressed in the paper are those of the authors alone, and in particular do not represent those of the International Monetary Fund.

¹Gerald Holtham and Andrew Hughes Hallett (1987) show that criteria can be applied that diminish the likelihood that coordination will be bad.

is the question of whether to evaluate gains *ex ante* or *ex post*. Our earlier paper focuses on the *ex ante* expected gains from coordination, while Frankel and Rockett (1988) consider the *ex post* actual gains after arbitrarily specifying which is the true model. The second issue concerns the nature of expectations formation. In our earlier paper, policymakers are assumed to have rational expectations across the set of possible models and to take due account of the presence of model uncertainty in formulating policies, whereas in Frankel and Rockett's approach policymakers are assumed to have different subjective priors with respect to the different models, but each believes (wrongly) that he/she knows the correct model.²

In this paper, we reexamine the issue of model uncertainty and policy coordination, highlighting the effects of the differences in approach described above. We use variants of a simple consensus open-economy model presented in Gilles Oudiz and Jeffrey Sachs (1985), which is based on the Rudiger Dornbusch (1976) extension to the Mundell-Fleming model.³ If the subjective priors of policymakers (and of private agents) equal the objective probabilities, the average of welfare values achieved *ex post*—presumably the relevant criterion—will equal the *ex ante* expected welfare value. This was the case in our earlier paper; here, we relax that assumption and allow subjective priors and objective probabilities to differ, as do Frankel and Rockett (but we do not allow for disagreement concerning these probabilities, as they do). We estimate alternative versions of the Oudiz-Sachs model and perform stochastic simulations on the assumptions that one or the other version is the true one and that agents assign nonzero

probabilities to each of the models; we use the *ex post* welfare criterion in evaluating the gains from coordination. However, policymakers are assumed to take account of the model uncertainty and to maximize expected utility over the range of models.

This paper also makes a significant departure from all of the earlier coordination literature in that it abandons the purely static view of model uncertainty which has hitherto been adopted. Instead, it is assumed that agents update their priors over the set of possible models in a Bayesian fashion.⁴ There is an extensive literature on "learning rational expectations" (William Brock, 1972; R. M. Cyert and M. E. De Groot, 1974; Stephen De Canio, 1979; Lawrence Blume and David Easley, 1982; Blume et al., 1982; Margaret Bray, 1982; Bray and Neil Savin, 1986; Albert Marcet and Thomas Sargent, 1988). The conclusion of this literature is that least-squares learning seems to converge to rational expectations in a wide variety of circumstances but that it may also converge to an incorrect model. In particular, the paper by Blume and Easley is closest to the setup of our paper, as the authors consider Bayesian updating of prior probabilities applied to a finite set of models. They construct examples of cases in which both the true model and the wrong model are locally stable (i.e., cases in which it is possible that agents do not converge to rational expectations). It is thus of interest to analyze in an empirical macroeconomic model whether convergence to rational expectations occurs both in a cooperative and in a Nash equilibrium. Furthermore, since the process of learning affects both policy-setting and the private sector's expectation formation, it will change

²In a section entitled, "Extensions with Uncertainty," Frankel and Rockett (1988) also consider cases in which models are not believed to be correct with certainty; however, priors are not rational in that the true objective probability does not equal the subjective prior.

³The multicountry models surveyed by Frankel (1988) are generally elaborations of this simple model structure.

⁴Frankel and Rockett (1988 p. 318) refer to this possibility in justifying their assumption of disagreement among policymakers but do not treat it formally: "If one wishes to think of actors as perpetually processing new information in a Bayesian manner, so that their models over time would converge on any given reality in the limit, then one must admit that the speed of convergence is sufficiently slow, or else that reality is changing sufficiently rapidly, that policymakers have not been able to reach agreement on the true model."

the economy's equilibrium and hence the estimated gains from coordination.

We evaluate three regimes: a cooperative equilibrium in which monetary policies (in particular, the monetary base) are jointly chosen to maximize a weighted average of the two countries' utilities; a noncooperative, or Nash, equilibrium in which each country maximizes its own utility, taking as given the actions of the foreign government; and finally a noninterventionist "pure float" exchange-rate policy, in which each country keeps the money supply at its exogenous target level. The models we use are based on an empirically estimated, two-country (United States and an aggregate rest-of-OECD [Organization for Economic Coordination and Development]) model with a number of structural variants. Although these structural differences are seemingly minor and innocuous, the differences in the reduced-form multipliers of the models are substantial, with the degree of model uncertainty similar to that in Frankel (1988).⁵ Policy conflicts between the countries arise from structural shocks to the world economy, including shocks to each country's money demand, aggregate demand, and inflation and to their joint exchange rate. In our simulation analysis, we use drawings from a joint distribution describing these shocks that is based on the empirically estimated covariance matrix.

Our main conclusions may be briefly summarized. First, if optimal policies—whether cooperative or noncooperative—assign sufficiently little weight to the true model and there is no learning, then the economy can become dynamically unstable with potentially large gains or losses from coordination. In contrast, uncoordinated policies involving freely floating exchange rates and exogenous money targets never result in dynamic instabilities in our estimated version of the Oudiz-Sachs model. Therefore, in the absence of model learning, such a

policy regime may be optimal, because it is more robust to model misspecification. We have argued previously (Ghosh and Masson, 1988) that the lesson from model uncertainty is not that coordination is bad, but that policy-setting—whether it is coordinated or not—should in some sense be more cautious. Our results here support that conclusion. Second, once Bayesian learning is allowed, optimal policies never result in dynamic instability, and even when very little initial probability is assigned to the true model, the *ex post* gains from coordination (when discounted back to the present) are *always* positive in our simulation exercises.

The reason for the latter result is simple. If policies are set to maximize *ex ante* expected utility, coordination only results in welfare deterioration *ex post* if the models are very different; in that case, however, it becomes very easy to distinguish between the models and to learn which is the true model. The subjective priors therefore quickly converge to the true model, and coordination is welfare-improving. We would not want to exaggerate the relevance of this result to real-world policy choice; instead, it highlights the inadequacy of the assumption that one model is the "true" one.⁶ Nevertheless, experience of the past quarter century does provide evidence that policymakers abandon views of the world that can be seen to be wrong (such as the view that there exists a long-run trade-off between unemployment and inflation that can be exploited by aggregate demand policy) and thereby avoid the more disastrous consequences of their actions.

I. The Empirical Model

The empirical model we adopt is a general, two-country Mundell-Fleming model with forward-looking exchange-rate expectations (see Dornbusch, 1976; Oudiz and

⁵The degree of model uncertainty for a particular reduced-form multiplier is measured in terms of the ratio of its squared average across models to the sum of its squared average and its variance.

⁶In the context of the quote in footnote 4, we would argue that the speed of learning is unlikely to be the source of the problem, but rather, that reality is much more complex than the models and is changing too rapidly.

Sachs, 1985). The model was estimated using the data that are the basis for the IMF's MULTIMOD model (Masson et al., 1988). Results are presented in Table 1, using the same notation as in Oudiz and Sachs (1985). Our two "countries" are the United States and the rest of the world (ROW); data for the latter region resulted from aggregation of the remaining industrial countries in MULTIMOD.⁷ The estimation period, using annual data, was 1966–1986. Aggregate demand equations were estimated using instrumental variables: the instruments included money stocks, government spending, time, and lagged prices and output.

The coefficient estimates are all of the right signs and are generally fairly well determined—in particular, the effects of the real exchange rate on U.S. aggregate demand and of U.S. GDP on rest-of-world demand, the money-demand parameters, and the change in GDP effects on the two regions' output price changes. Despite its simplicity, the model seems to fit the data fairly well. Nevertheless, residual serial correlation is evident in the money-demand equations, and the specification embodies arbitrary constraints that are open to discussion. We proceed to relax some of these restrictions below and to estimate the resulting alternative models.

The computational burden of calculating optimal policies with model learning severely restricted the number of alternative models we could introduce; in this paper, we consider three possible models. The two alternative models, models II and III, differ from the baseline model (model I) in two respects: in model II money balances are deflated by the consumer price index rather than the GDP deflator, and there is a lagged dependent variable in the money-demand

equation, while in model III there is also a nonvertical Phillips curve. Estimates for these models are also presented in Table 1.

A first arbitrary feature of model I relates to the proper deflator for real money balances. As William Branson and Willem Buiter (1983) point out in their discussion of the Mundell-Fleming model, the effects of monetary and fiscal policies can be importantly different depending on whether the domestic output price or a broader index that includes foreign goods is used. The Oudiz-Sachs specification, excluding as it does the effects of terms of trade, conforms in this respect to the original Mundell-Fleming model. Model II deflates money balances not by p but by p^c . A second major area of arbitrariness in the Oudiz-Sachs model is the dynamic specification. The money-demand equation, whether specified with the output or consumption deflator, shows evidence of residual serial correlation. Most studies have allowed for the possibility that money balances adjust with a lag and have included a lagged dependent variable (see e.g., Stephen Goldfeld, 1973); this is also done in model II. The resulting money-demand equations fit considerably better than the ones in model I.

Model III includes the changes of model II and also relaxes the unitary coefficient on the lagged rate of inflation in the domestic-price-change equation. Relaxing this restriction lowers the standard errors of estimate in both the U.S. and rest-of-world equations, and the standard errors for the inflation coefficients imply rejection of the unitary coefficient for both the United States and the rest of the world. Furthermore, the change in output becomes insignificant, so we dropped this variable. Though the fit of the equations is only marginally superior to that for model I, the two specifications for the inflation equation have quite different long-run properties. The Oudiz-Sachs model exhibits no long-run trade-off between output and inflation, as in the steady state both output prices and consumer prices grow at the same, steady rate. In contrast, with a nonunitary coefficient, different rates of inflation are associated with different rates of

⁷In general, variables were aggregated by converting to a common currency and summing. GDP (gross domestic product) weights were used to aggregate interest rates. The exchange rate was taken to be the reciprocal of the MERM-weighted effective rate (Jacques Artus and Anne McGuirk, 1981) of the U.S. dollar (in index form, 1980 = 1). The rest-of-world price level and money supply are expressed in this "currency."

Variable Definitions	
(U.S. variables are unstarred; non-U.S. variables are starred; all variables except i and t are in logs)	
e = nominal exchange rate (dollars per foreign currency)	
g = real government spending on goods and services	
i = nominal short-term interest rate	
m = monetary base	
p = GDP deflator	
p^c = deflator of domestic absorption	
q = real GDP	
t = time trend	

TABLE 2—EIGENVALUES OF MODELS I–III

Model I	Model II	Model III
1.421	1.237	1.195
0.975	0.982 ± 0.069i	0.942
0.936 ± 0.119i	0.974	0.782
−0.085	0.611	0.656
	−0.363	0.237
	−0.044	

output growth; this possibility would be disputed by many economists, however (see e.g., Milton Friedman, 1968). On the basis of the estimation results, it may be reasonable to attribute some nonzero probability to the existence of such a trade-off.

Although the structural differences among the three models seem minor, the reduced-form multipliers differ considerably across the models, as do the dynamic properties (see Table 2 for the eigenvalues of the three models). There is one unstable eigenvalue in each case, corresponding to the one nonpredetermined variable, the exchange rate. Model II has a more complicated dynamic structure and two extra real eigenvalues, compared to model I: this is due to lags in money demand. Model III retains the money-demand equation but has a simpler adjustment process for prices.

A simple summary statistic for the degree of model uncertainty is given by the ratio

$$(1) \quad \zeta = \mu^2 / (\mu^2 + \sigma^2)$$

where μ is the mean multiplier of an instrument on a particular target and σ^2 is its variance (across the three models). This gives a dimensionless statistic which equals unity if there is no model uncertainty and approaches zero as the effectiveness of the policy instrument deteriorates, in the sense of William Brainard (1967). In a model with forward-looking variables, the multipliers depend upon the anticipation of future policies as well as current policies and therefore are not independent of the regime under consideration (it is assumed for this purpose that a policy of exogenously setting the money supply prevails).

Table 3 includes the second-year multipliers for the three models, as well as ζ values, for an exogenous permanent increase in the money supply of 4 percent. As expected from theoretical models, the transmission effects of a monetary expansion can have either sign, depending on parameter values: models I and II imply positive transmission onto foreign output, while the reverse is true of model III. Somewhat surprisingly, the second-year *domestic* output effects of a ROW money increase also are ambiguous: the negative effect on ROW output in models I and II results from the large coefficient on the lagged change in output in the ROW inflation equation, which pushes up domestic output prices by enough that the real exchange rate appreciates in the second year relative to baseline.⁸ In model III, ROW output effects of a ROW monetary expansion are persistently positive. Though models I and II give the same signs for all the multipliers, their numerical values differ substantially.

It is interesting to compare the ζ values for our three models with those implied by the models in Frankel's (1988) study, also calculated for such a money-supply shock. As can be seen from Table 3, his study of 12 different models incorporates a somewhat greater degree of uncertainty about the reduced-form multipliers of a U.S. monetary expansion than our three alternative models, but the output effects of a ROW monetary expansion are more certain in Frankel's set of models than in ours.

II. Optimal Policies Under Model Uncertainty and Model Learning

In order to calculate the average *ex post* gains from coordination with model learning, we adapt the algorithm we developed in Ghosh and Masson (1988). The logic of the model is as follows. In period t , the state vector \mathbf{x}_t and a vector of subjective priors

⁸In the *first* year, the money supply increase leads to a large increase in ROW output, however: by 2.8 percent in model I and by 2.2 percent in model II.

TABLE 3—REDUCED-FORM MODEL MULTIPLIERS AND MEASURES OF MODEL UNCERTAINTY

Model	Effects of U.S. money supply on:				Effects of ROW money supply on:			
	U.S. Y	ROW Y	U.S. P	ROW P	U.S. Y	ROW Y	U.S. P	ROW P
<i>Second-year effects of a 4-percent monetary expansion (percentage):</i>								
I	0.5	1.0	1.2	-2.6	0.2	-0.1	-0.8	3.8
II	0.2	0.2	0.9	-1.8	0.1	-0.4	-0.6	3.1
III	0.5	-0.2	0.8	-0.4	-0.2	0.5	-0.5	1.0
<i>Measures of model uncertainty (ζ values; percentage):^a</i>								
I-III	88	31	97	75	4	— ^b	96	83
Frankel (1988)	68	— ^b	45	52	19	72	24	25

^aBased on second-year effects; a smaller number indicates greater uncertainty.

^bThe effects were clustered around zero, giving a zero value for ζ .

Π_t (with elements π_t^i) are inherited. Policymakers choose a vector of controls (i.e., policy instruments) u_t in order to influence their target vector τ_t . They do not attempt active learning (i.e., performing policy experiments in order to discover which of the models is correct). At the end of period t , a vector of endogenous variables ω_{t+1} is observed which allows agents to update their priors, yielding Π_{t+1} .

The dynamics of the world model are assumed to be given by:

$$(2) \begin{bmatrix} x_{t+1}^i \\ e_{t+1}^i \end{bmatrix} = \begin{bmatrix} A^i & B^i \\ D^i & F^i \end{bmatrix} \begin{bmatrix} x_t^i \\ e_t^i \end{bmatrix} + \begin{bmatrix} C^i \\ G^i \end{bmatrix} u_t + \begin{bmatrix} \Theta_x^i \\ \Theta_e^i \end{bmatrix} \varepsilon_t$$

for i ranging over the possible models i, \dots, k , and where x is a vector of state variables, e is a vector of jumping variables, u is the vector of controls, and ε is an unobserved vector white-noise shock, distributed $N(0, \Sigma)$ (Σ is the variance-covariance matrix). $A^i, B^i, C^i, D^i, F^i, G^i, \Theta_x^i$, and Θ_e^i are constant matrices associated with model i .

In addition, structural equations of the models map the state variables and the forward-looking variables into a vector of targets τ :

$$(3) \tau_t^i = L^i x_t + M^i e_t + N^i u_t + \Theta_\tau^i \varepsilon_t.$$

Policymakers in each country are assumed to have preferences over the target vector which are represented by

$$(4) v = \max \left[- (1/2) \sum_{t=0}^{\infty} \beta^t E \{ \tau_t' \Omega \tau_t \} \right]$$

and

$$(5) v^* = \max \left[- (1/2) \sum_{t=0}^{\infty} \beta^t E \{ \tau_t' \Omega^* \tau_t \} \right]$$

respectively, where β is a discount factor, Ω and Ω^* are matrices that weight the target variables, and the expectation is taken with respect to uncertainty about both the correct model and the current realization of the shock ε_t . We assume that, although agents do not know the true model of the world economy, they do know the variance-covariance matrix of the additive shocks.⁹ Moreover, we do not allow heterogeneity of agents; both the private sectors and the governments start with the same priors across models and update them in the same fashion.

Following Oudiz and Sachs (1985), we derive the optimal linear decision rules by first calculating the dynamic programming

⁹This is a somewhat heroic assumption, but it simplifies the analysis considerably. Furthermore, our main conclusions do not appear to be excessively sensitive to the assumed variance-covariance matrix.

solution¹⁰ for a (finite) T -period horizon and then increasing T until stationary matrices Γ and Γ^* (functions of Π_t) are obtained:

$$(6) \quad \mathbf{u}_t = \Gamma(\Pi_t)\mathbf{x}_t \quad \text{and} \quad \mathbf{u}_t^* = \Gamma^*(\Pi_t)\mathbf{x}_t.$$

Moreover, this allows us to write the vector of forward-looking variables as a linear function of a matrix λ and the state vector \mathbf{x}_t :

$$(7) \quad \mathbf{e}_t = \lambda(\Pi_t)\mathbf{x}_t.$$

From equations (2)–(7), we can then express the value functions as quadratic forms in \mathbf{x}_t and matrices \mathbf{S} and \mathbf{S}^* (dependence on \mathbf{x}_t and Π_t is made explicit by the functional notation):

$$(8) \quad v(\mathbf{x}_t, \Pi_t) = \mathbf{x}_t' \mathbf{S}(\Pi_t) \mathbf{x}_t$$

$$v^*(\mathbf{x}_t, \Pi_t) = \mathbf{x}_t' \mathbf{S}^*(\Pi_t) \mathbf{x}_t.$$

Once the optimal stationary policy rules have been obtained, the model is simulated forward, and priors are updated using Bayesian inference. The forward simulation is conditional on a particular model, say model j , being true. Suppose that in period t , the world economy has inherited the state \mathbf{x}_t and priors over the models are given by Π_t . The optimal policy in period t for the home country is given by

$$(9) \quad \mathbf{u}_t = \Gamma(\Pi_t)\mathbf{x}_t.$$

A drawing from the shocks \mathbf{e}_t is made, and the state vector in $t+1$ is therefore given by

$$(10) \quad \mathbf{x}_{t+1} = \mathbf{A}^j \mathbf{x}_t + \mathbf{B}^j \lambda^j(\Pi_t) \mathbf{x}_t \\ + \mathbf{C}^j \mathbf{u}_t + \Theta_{\mathbf{x}}^j \mathbf{e}_t.$$

At the beginning of period $t+1$, agents

observe a vector of variables ω_{t+1}^i . Each of the k possible models implies a structural relationship for the observation vector ω_{t+1}^i

$$(11) \quad \omega_{t+1}^i = \mathbf{W}_{\mathbf{x}}^i \mathbf{x}_t + \mathbf{W}_{\mathbf{e}}^i \mathbf{e}_t + \mathbf{W}_{\mathbf{u}}^i \mathbf{u}_t + \mathbf{W}_{\mathbf{e}}^i \mathbf{e}_t,$$

where matrices $\mathbf{W}_{\mathbf{x}}^i$, $\mathbf{W}_{\mathbf{e}}^i$, $\mathbf{W}_{\mathbf{u}}^i$, and $\mathbf{W}_{\mathbf{e}}^i$ are obtained from the relevant rows of (2) and it is assumed that $\mathbf{W}_{\mathbf{e}}^i$ is invertible.¹¹

Let $E(\omega_{t+1}^i)$ be the expected value of ω_{t+1}^i [evaluated at $E(\mathbf{e}_t) = \mathbf{0}$]. The value of the shock implied by each model is therefore

$$(12) \quad \mathbf{e}_t^i = (\mathbf{W}_{\mathbf{e}}^i)^{-1} [\omega_{t+1}^i - E(\omega_{t+1}^i)].$$

The new Bayesian priors are then given by

$$(13) \quad \pi_{t+1}^i = \frac{\Pr(\mathbf{e}_t^i | \Sigma^i) \pi_t^i}{\sum_{i=1}^k \Pr(\mathbf{e}_t^i | \Sigma^i) \pi_t^i}$$

where $\Pr(\cdot)$ is the probability that a vector shock, distributed $N(0, \Sigma^i)$, takes the value \mathbf{e}_t^i . The state variables in period $t+2$ are then generated with a drawing for \mathbf{e}_{t+1} , and the whole process is repeated.¹²

III. Simulation Results

In addition to the model parameters, the simulation analysis requires specification of the policymakers' discount factors (chosen to be 0.95; i.e., a discount rate of 5 percent per annum), the utility weights on each target, and the relative weight each country receives in the social planner's objective function. The utility weights were taken from the revealed preference estimates of Oudiz and Sachs (1984) with policymakers assumed to target inflation and output.¹³

¹¹If agents observe fewer variables than the number of shocks in \mathbf{e}_t , then they face a signal-extraction problem concerning the shocks as well as the models.

¹²Until the priors converge to the model generating the data, expectations will not be unbiased.

¹³The current-account objective in Oudiz and Sachs (1984) was ignored. The utility-function weights used were those reported in table 11 of their paper; for the rest of the world, weights for Japan and West Germany were averaged.

¹⁰The dynamic programming solution excludes trigger mechanisms and reputational strategies. It may therefore exaggerate the gains from coordination relative to Nash solutions (see Matthew Canzoneri and Dale Henderson, 1988).

The objective functions are as follows for the United States (unstarred) and the rest of the world (starred):¹⁴

(14)

$$V = E \left\{ \sum_{t=0}^{\infty} 0.95^t [0.07q_t^2 + 0.49(\Delta p_t^c)^2] \right\}$$

(15)

$$V^* = E \left\{ \sum_{t=0}^{\infty} 0.95^t [0.045q_t^{*2} + 0.50(\Delta p_t^{c*})^2] \right\}.$$

The world objective function is

$$(16) \quad V_w = \alpha V + (1 - \alpha)V^*.$$

In simulations reported below, $\alpha = 0.5$; each country is given equal weight in the world objective function, which is used to evaluate the outcomes of the three policy regimes.¹⁵

In the Nash equilibrium, the United States maximizes (14) with respect to m_t , and the rest of the world maximizes (15) with respect to m_t^* . In the cooperative regime, (16) is maximized with respect to $\{m_t, m_t^*\}$. In the floating regime, policy is

described by an exogenous money-supply target, whatever the value of the objective functions. The observation vector includes output, interest rates, and producer prices in each country and the nominal exchange rate. The optimal policies and value functions depend nonlinearly on the probabilities assigned to each of the three models. The recursive optimization had to be done on a two-dimensional grid; that is, for each possible combination $[\pi^1, \pi^2, (1 - \pi^1 - \pi^2)]$, the recursive algorithm outlined above must be solved.¹⁶

In the first set of simulations, all agents assign an initial probability to each model and do not update their priors (to repeat, we assume throughout that all agents in the model—both private and public—share a common set of subjective priors). The results are reported conditional on each of the three models being the true model; we also cite results for the certainty case, in which agents assign a probability of 1 to the true model. The values reported in Table 4 represent the total present value of disutility for the world economy (with equal weights on the United States and the rest of the world) and are expressed in terms of GDP equivalents. As is evident below, some of the simulations exhibit explosive behavior, and the present value of disutility may be undefined; in these cases, we have simply marked the entry “explosive.” Since there is an additive random shock, ϵ_t , disutility depends upon the specific realizations (which are drawn from a normal distribution with zero mean and the estimated variance-covariance matrix of the “true” model),¹⁷ and hence we have taken the average of ten stochastic simulations (the drawings are the same for each of the models). The optimal

¹⁴ Variables q and Δp^c are output and the rate of change of consumer prices, both as deviations from the baseline.

¹⁵ The welfare values in Table 4 are all for world welfare, using the same equally weighted objective function. There is no guarantee that both countries' welfares increase as a result of cooperation (although in most cases both do). We have verified that, in all cases where coordination improves world welfare, a set of weights could be found such that each country's welfare (averaged over the ten drawings of the shocks) was higher. In practice, when unequal weights were necessary, a greater weight had to be given to the United States than to the rest of the world in world welfare, no doubt a result of asymmetries in the multipliers reported in Table 3. Such welfare weights, however, lowered the overall gains from cooperation, when evaluated using a consistently defined objective function. Alternatively, if a mechanism for side payments existed, then both countries would always gain, even when cooperation involved maximizing the equally weighted welfare function.

¹⁶ We used a grid of 11 equally spaced intervals. Table 4 reports a subset of those simulations, plus simulations in which a very small weight (0.045) is placed on the true model, and others in which a weight of 0.5 is placed on the true model and weights of 0.25 are placed on the alternative models.

¹⁷ None of the estimated correlations between shocks was significant at the 5-percent level, so a diagonal variance-covariance matrix was used to generate the shocks.

^bTable entries are initial probabilities; probabilities are updated in a Bayesian fashion.

policies are designed to stabilize output and inflation against the specific random structural shocks applied to the model; as such, the optimal policies under both cooperative and noncooperative behavior are not easily interpretable and are therefore not reported.

There are two noteworthy points about the top part of Table 4 (no model learning). First, when equal weights are assigned to the competing models and a weight of 0.5 is assigned to the "true" one, the gains from coordination relative to the Nash equilibrium are not spectacular but are certainly measurably positive: they are comparable in size to those under certainty (the top line of each panel). These gains, which range from 6 percent to 13 percent of GDP, amount to a permanent increase of about half of 1

percent of GDP per year (using the 5-percent discount rate), an estimate which is in line with those of previous studies (e.g., Oudiz and Sachs [1984], who calculate welfare gains in that form to be less than 1 percent).¹⁸ Both the Nash and the cooperative equilibria are significantly better than a pure float regime for model I; this is not true of model III, however, where floating is intermediate between the other two regimes. For model II, under certainty, the Nash equilibrium is better than floating; but with a probability of 0.5 on model II and 0.25 on models I and II, the Nash equilibrium is

¹⁸In Oudiz and Sachs (1984), the gains are given in terms of GDP equivalents sustained for three years.

considerably worse and the cooperative regime is somewhat worse than the pure float regime.

Second, when we assign a low probability to the true model and a high probability to one of the competing models, the cooperative regime actually yields substantially lower *ex post* welfare than the pure float regime. The situation is most critical when a large weight is attached to model III (and either model I or model II is correct); here, the cooperative solution results in (eventually) explosive behavior¹⁹ of the economy or in large disutility. The Nash equilibrium also implies large (and in some cases, unbounded) disutility when the weights are over 90 percent on model III but one of the other models is correct. In fact, the most robust policy to follow is one of complete nonintervention. The large losses and possible instability no doubt result from the fact that model III implies a long-run trade-off between output and inflation, which activist policies (either Nash or cooperative) try to exploit—unsuccessfully, it turns out, because the true model, either model I or model II, is in fact a natural-rate model. In either case, coordination severely reduces welfare to the extent of making the sustainability of a coordinated regime infeasible. However, it is important to note that it is not only the cooperative regime that may result in low welfare when policymakers use the wrong model. For example, if model II is the true model but a high prior (0.9) is put on model III, the Nash equilibrium is highly inefficient, so that there are very large *gains* from coordination. In the cases when both cooperative and Nash equilibria exhibited instability, the disutility levels were larger and diverged more quickly for the latter.

The conclusion that emerges from the above results is therefore that a policy rule that does not require active intervention, corresponding to exogenous money supplies

and floating exchange rates, is the safest policy when policymakers are uncertain about the model. Our results therefore provide some support to the advocacy of fixed rules in preference to activist policies, which Friedman has long argued may be destabilizing (see e.g., Friedman, 1948).²⁰

The results suggest that, when policymakers have the wrong priors over the models and do not undertake updating, any policy intervention—coordinated or uncoordinated—can be dangerous. However, it is implausible that policymakers would not update their subjective priors when they find that their expectations about the effects of their policies are consistently invalidated. In a second set of simulations, therefore, we assume that agents update their priors over the models in the Bayesian fashion described above. The lower part of Table 4 reports the discounted present value of disutility under cooperative and noncooperative behavior, as well as the floating-exchange-rate regime with exogenous money targets, for simulations with various initial probability priors.

The important conclusion that emerges is that policies no longer become unstable, even when the initial priors attributed to the true model are very low. Furthermore, we find that coordination is always welfare-improving relative to both the Nash equilibrium and nonactivist policies. Consider, for example, the case in which agents assign a prior probability of 4.5 percent to model I and 95.5 percent to model III, when model I is the correct model. In the absence of Bayesian updating, coordination reduces welfare substantially relative to a pure float, since the coordinated regime is dynamically unstable. Bayesian learning, combined with the same initial priors, results in a welfare gain relative to both Nash equilibrium and floating.²¹ With endogenous model-learning,

¹⁹The instability manifested itself in a failure of policy settings to converge, and in the fact that disutility levels were not bounded as the horizon was extended.

²⁰There are other considerations that are relevant to the choice between fixed rules and more activist policies (see e.g., Stanley Fischer, 1988).

²¹Nevertheless, a superior policy *ex post* would have been to follow a noninterventionist policy until policymakers reduced their probability weight on the incor-

ing, the discounted-present-value gains from coordination are all in the range of 7–15 percent of GDP.²² The noninterventionist-policy regime now performs consistently worse than the cooperative regime but is sometimes better than the Nash equilibrium—in particular, when model III (the non-vertical Phillips curve model) is true. In this case, it would seem that the scope for beggar-thy-neighbor policies is greater; they are ruled out by both the cooperative and “floating” (i.e., nonactivist) regimes.

The examples in which policymakers (and the private sector) assign a high initial weight to model III, when in reality one of the other two models is correct, have some relevance to the history of demand management in the postwar period. Early models of the “Phillips curve” (see e.g., A. W. Phillips, 1958; Richard Lipsey, 1960) implied that there was a trade-off between the rate of change of wages or prices and the unemployment rate or output. These models no doubt helped induce central banks and treasuries to engage in demand expansion, in an attempt to buy more output growth at what was judged to be an acceptable inflation cost. The experience of accelerating inflation beginning in the late 1960’s forced economists and policymakers to reconsider those models, and there has been a profound shift in policy away from short-term fine-tuning and to a concern for the medium-term inflation consequences of policy. Moreover, the rationale for the policy changes has been acceptance of natural-rate models, which do not allow for monetary stimulus to have permanent positive effects on the level of activity. Friedman (1977 p. 470) commented on the change in policy in the following terms in his Nobel lecture:

Government policy about inflation and unemployment has been at the center

of political controversy. Ideological war has raged over these matters. Yet the drastic change that has occurred in economic theory has not been a result of ideological warfare. It has not resulted from divergent political beliefs or aims. It has responded almost entirely to the force of events: brute experience proved far more potent than the strongest of political or ideological preferences.

IV. Caveats and Discussion

Having found that, in the presence of model-learning, the cooperative regime dominates noncooperation and nonintervention in the context of our model, we tried to gauge the sensitivity of the results to our assumptions. The *ex post* performance of the coordinated regime depends on two factors: the robustness of the optimal policy to model errors; and the rate of learning of the model. Clearly, the more diverse the models are, the more likely the optimal policy based on the “wrong” priors is to result in lower welfare. We also thought that we might have assumed too little uncertainty in choosing the structurally similar models of Section III. However, in further simulations with more diverse models, we found that as the degree of model uncertainty increased (in the sense of lower ζ ratios) the rate of model-learning also increased. The intuition is straightforward: if the models are very different, then the implied observation vector of each model is also very different, and the updated priors assigned to the false models will be correspondingly low. Thus, although greater diversity between the models makes more likely the possibility of welfare-deteriorating policies, it also serves to reduce the model uncertainty (at least when there is a finite number of alternative models, as is the case here).

It is possible to decrease the rate of learning by increasing the variance of the additive shocks ϵ_t . The greater the variance of ϵ_t , the greater the noise in the updating observations and, therefore, the slower the rate of learning. We checked the sensitivity of our results by using a variance matrix with ten times the estimated standard er-

rect model (model III) sufficiently and then cooperated.

²² When the world objective function uses weights that ensure that welfare averaged over the ten stochastic simulations improves in both countries as a result of cooperation, the range of gains is 1.5–15 percent.

rors. Despite this large increase in error variances, however, we were unable to reverse our conclusions about the ranking of the coordinated and uncoordinated regimes in the presence of learning.

It must be emphasized, however, that our experiments assume knowledge of the variance-covariance matrix describing the shocks. Forcing agents to estimate it would introduce considerably more uncertainty and make it more difficult to infer which model was correct, as would a combination of temporary and permanent shocks.

Another caveat is that we have simplified the problem to one in which policymakers must just discover the unique unchanging model describing the economy. An alternative assumption is that agents can never perfectly anticipate the true model when setting policies, because the true model is stochastic. If the vector of subjective priors converges to the true probability that the model is realized, then the average *ex post* welfare gain will equal the *ex ante* expected welfare gain from coordination, at least in large samples. In that case, we return to the *ex ante* expected welfare criterion in which coordination is necessarily welfare-improving.²³ More realistic is the case in which the true model is changing in a nonrandom way as a result of structural shifts and in which these shifts occur frequently enough so that the distribution describing the models is never completely learned. We have yet to explore this case.

V. Conclusions

In this paper, we have discussed whether coordination is likely to reduce the actual *ex post* level of welfare when policymakers are uncertain about the effects of policies. We have found no evidence in our simulations that policy coordination is likely to reduce welfare vis-à-vis noncooperative policies; however, a simple nonintervention

regime, such as a pure floating exchange rate accompanied by exogenous money targets, may be the most robust policy in the presence of model uncertainty. These conclusions are of course specific to a particular model and are based here on an estimated version of the Mundell-Fleming model with sticky prices and rational exchange-rate expectations. More experimentation with other models is no doubt necessary in order to gauge whether the conclusions can be generalized.

Once we introduced endogenous model-learning, we found that coordination always results in higher welfare: though the gains from coordination are not spectacular, they appear to be significantly positive. We were unable to generate losses from coordination, even by increasing the variance of the additive noise. No doubt, the representation of the economy is much too simple. What the results suggest, however, is that the conclusion that coordination is as likely to decrease welfare as to increase it (see Frankel and Rockett, 1988) is not consistent with the joint assumptions that there is a single "true" model and that agents learn about that model in a Bayesian fashion.

Welfare Dominance: An Application to Commodity Taxation

By SHLOMO YITZHAKI AND JOËL SLEMROD*

In this paper, we propose a method to identify commodity-tax changes that will be favored by all individuals who can agree on certain weak assumptions with regard to the social-welfare function. The method is based on an extension of the criterion of second-degree stochastic dominance and is illustrated using data from Israel. (JEL H21)

A principal weakness of the theory of optimal taxation with heterogeneous taxpayers is the dependence of the optimum tax rates on the exact properties of the social-welfare function. While other components of the problem, such as the excess burden of the tax system, can presumably be reconstructed from empirical observations on the behavior of consumers, it is clear that estimating the social-welfare function is not an easy task. Although there have been several attempts to recover the social-welfare function using the revealed preferences of governments (usually by assuming that governments act optimally according to a "just" principle of taxation, such as equal sacrifice), all these methods require very strong assumptions which are unlikely to command wide support (see Richard Musgrave, 1959; Koichi Mera, 1969; Burton Weisbrod, 1968; John Piggott, 1982; Menahem Yaari, 1988).

This problem is especially disturbing for developing countries that rely heavily on commodity taxes as a major policy instrument for raising revenues, dealing with poverty, and changing the income distribu-

tion. In most of these countries, data are not available even for estimating the excess burden of the tax system. Therefore, it seems that the theory of optimal commodity taxation is not very helpful as an input into policy formulation in this context. This problem is even more complicated from the perspective of an economic adviser whose role is to advise the government of a specific country. If, in an ideal case, the government can supply him or her with all the necessary data, then the "cost" or the inefficiency caused by the tax system can be estimated. However, in order to make recommendations about optimal tax design, the adviser must be aware of the preferences of the government (or the society) involved. Without this information, the advice rendered represents only the adviser's preferences, which need not be the same as those of the government seeking advice. Hence, there is interest in examining the possibility of overcoming this difficulty by statistical analysis.

The aim of this paper is to suggest a method that enables the user to identify commodities that a large class of social-welfare functions would reveal as being worth subsidizing or taxing. If such commodities can be identified, then the task of advising the government on optimal directions of tax reform will be rendered nearly value-free. Alternatively, nearly all social-welfare functions would indicate that the taxation of one commodity should be reduced in favor of heavier taxation on another.

The specific question this paper addresses is the following. Assume that the social evaluation of the marginal utility of income

*Hebrew University, Jerusalem 91905, Israel; University of Michigan, Ann Arbor, MI 48109. The first version of the paper was written while Yitzhaki served as a consultant at the World Bank. The World Bank does not accept responsibility for the views expressed herein, which are our own and should not be attributed to the World Bank or to its affiliated organizations. We thank Reza Firuzabadi for research assistance and Joram Mayshar, Wayne Thirsk, and three anonymous referees for their comments.

is positive and declining. The government plans to make an equal-yield change in its commodity-tax system by subsidizing one commodity and taxing another commodity by one additional dollar. Is it possible to identify two such commodities such that welfare increases for all additive concave social-welfare functions? If such situations can be identified, a preferred direction of tax reform can be located without detailed knowledge of preferences regarding interpersonal transfers. If such commodities *cannot* be found, it will clearly be impossible to make recommendations in the absence of further information about the governing social-welfare function.

The methodology that enables us to answer such questions was originally developed in the finance literature, where it is referred to as the "second-degree stochastic dominance" criterion. The main idea is to rank portfolios according to their expected utility, such that the investigator assumes only that the marginal utility of income is nonnegative and nonincreasing. Based on these assumptions, rules for ranking prospects have been developed (e.g., Josef Hadar and William Russell, 1969; Giora Hanoach and Haim Levy, 1969).

Our intention is to use the methodology of stochastic dominance to evaluate changes in the taxation of commodities. As has been demonstrated by Anthony Atkinson (1970), there is a formal similarity between the ranking of income distributions and the ranking of prospects. Hence, the use of stochastic-dominance rules in welfare economics is a natural development following from Atkinson's observation. However, since taxation (in particular, commodity taxation) affects social welfare in a slightly different way than the effect of a portfolio on the utility function, several changes must be made in the methodology. We refer to these adapted rules as welfare dominance.¹ The major changes are the following:

- (a) In the finance literature, the main interest is to rank portfolios, the analogy to

which, in our study, is the ranking of income distributions. Our goal, though, is the ranking of (taxes on) commodities, expenditure on which is only one component of total income. Therefore, we have to use conditional stochastic-dominance rules. The analogy in the finance literature is the issue of whether asset A dominates asset B, given that the investor also has to hold portfolio C. In the case of welfare dominance, the same formal question can be interpreted as whether subsidizing expenditure on commodity A financed by a tax on commodity B improves social welfare, given that the income distribution is C.

- (b) We will be interested in dominance at the margin. The analogy to finance is whether a small increase in the share of asset A at the expense of asset B (given that the rest of the portfolio held is C) increases expected utility. In the case of taxation, the same formal question is now whether a small decrease in the tax on commodity A financed by a small increase in a tax on B (given that the income distribution is C) increases social welfare.
- (c) In welfare economics, one has to take into account the efficiency implications of the reform. This means that an increase of one dollar in the revenue from the tax on one commodity enables the government to subsidize another commodity by an amount that may be larger or smaller than one dollar, depending on efficiency considerations.

As we show in the next section, this question can be answered by comparing shifted concentration curves. The concentration curve is a diagram similar to the Lorenz curve. On the horizontal axis the households are ordered according to their income, while the vertical axis describes the cumulative percentage of the total expenditure on a specific commodity that is spent by the families whose incomes are less than or equal to the specified income level. The concentration curve, like the Lorenz curve, passes through the origin; but, unlike the

¹This term was coined by Anthony Shorrocks (1983).

Lorenz curve, it need not always be increasing, and its curvature depends on the structure of the income elasticity of the commodity. In particular, if the curve is convex (concave) to the origin, then the income elasticity is negative (positive).² Efficiency implications of the reform result in shifts of the concentration curves.

We demonstrate that if the (shifted) concentration curve of one commodity is above the (shifted) concentration curve of another commodity, then the first commodity dominates the second in the sense that a small tax decrease in the first accompanied by a tax increase in the second (with revenue remaining unchanged) increases social welfare. However, if the (shifted) concentration curves intersect, then it is impossible to show dominance. In other words, if and only if concentration curves do not intersect will all additive social-welfare functions show that the tax change increases welfare.³ We refer to these rules as "marginal conditional stochastic dominance" rules (hereafter MCSD rules). In the remainder of the paper, we will use the term "dominate" when one commodity has marginal conditional stochastic dominance over another.

The next section provides an intuitive proof for MCSD rules. In the second section, additional insight is gained by relating these rules to a methodology based on the decomposition of the Gini coefficient. Section III uses data from Israel to illustrate the methodology. The paper concludes with suggestions for further research.

I. Intuitive Derivation of the Methodology⁴

Assume that tax policies are evaluated according to an additively separable social-welfare function.⁵ All that is known about the social-welfare function is that the social evaluation of the marginal utility of income is positive and declining. Formally,

$$(1) \quad W = \sum_h w[v^h(y_h, P_1, \dots, P_n)]$$

where y is income and the P 's are prices, v is the indirect utility, and w is the social evaluation of the utility of individual h . Individuals may have different utility functions. However, we assume that if $y_i = y_j$ then $w[v^i(y, P_1, \dots, P_n)] = w[v^j(y, P_1, \dots, P_n)]$ and that the social evaluation of the marginal utility of income, denoted β , is a function of y (and prices) only.⁶ That is, $\beta(y) = (\partial w / \partial v^h)(\partial v^h / \partial y)$ is a positive and declining function of y with $\partial \beta / \partial y < 0$. We refer to β as marginal welfare.

Now suppose the government is considering a small increase in the tax on commodity t and a small decrease in the tax on commodity s , so that total revenue does not change. Let x_i^h denote the consumption of commodity i by the h th individual, where individuals are arranged in nondecreasing order of income, and let X_i denote total consumption of commodity i . Since the change in revenue raised is zero, there is a link between the change in the prices of

²For a detailed analysis of the curvature of concentration curves, see Nanak Kakwani (1980) and Yitzhaki and Ingram Olkin (1988).

³It is worth noting that concentration curves have long been used to describe the progressivity of taxes (see, e.g., Daniel Suits, 1977a,b; Charles Clotfelter, 1979; John Formby and David Sykes, 1984; Formby et al., 1986a,b; Kakwani, 1977a,b, 1980; Thomas Calmus, 1981; Pak-Wai Liu, 1985; Donald Kiefer, 1984). However, the use of concentration curves to identify welfare-improving tax changes is new. As will be shown later, this interpretation requires several adjustments to the way concentration curves are defined.

⁴In Yitzhaki and Olkin (1988), MCSD rules are developed in the context of portfolio analysis. Since the proofs are similar to those required in this paper, we refer the interested reader to that paper. In this section, an intuitive proof is given.

⁵The results of the paper also apply to an increasing, S-concave, social-welfare function. The requirement for an additive social-welfare function enables us to present intuitive proofs.

⁶Income is defined here in a broad sense, so that it can be interpreted as income per capita, income divided by the poverty ratio, etc. All that is required is that, if the income of one individual is higher than the income of another individual, then the welfare of the first individual is higher than the welfare of the second.

commodities t and s . Let R be the tax revenue. Assuming that there are K taxed (subsidized) commodities and that producer prices are normalized to 1, then:

$$(2) \quad R = \sum_k \tau_k X_k$$

where τ denotes the tax (or subsidy) rate. Reducing the tax on (subsidizing) commodity s and increasing the tax (reducing subsidy) on commodity t while keeping tax revenue unchanged implies that

$$(3) \quad dR = 0 = dP_t X_t \alpha_t + dP_s X_s \alpha_s$$

where $\alpha_i = 1 + \sum_k (\tau_k / X_i) (\partial X_k / \partial \tau_i)$. P_i refers to the consumer price i , so that $P_i = 1 + \tau_i$. The term α_i reflects the revenue effect of a change in τ_i ; in general, it depends on all tax rates and the properties of the demand functions. David Wildasin (1984) and Joram Mayshar (1988) interpret α_i as the marginal social cost of raising one dollar of revenue by taxing the i th commodity. Rearranging terms, equation (3) can be written as

$$(4) \quad dP_t = - (X_s / X_t) \alpha_{st} dP_s$$

where $\alpha_{st} = (\alpha_s / \alpha_t)$ can be interpreted as the ratio of the marginal costs of public funds. If $\alpha_{st} < 0$, then both prices can be decreased while holding revenue constant.⁷ Since this is a trivial case, it is assumed that $\alpha_{st} > 0$. We consider other important values of α_{st} in the next section.

Now consider the change in the utility of individual h when tax rates are changed. Denote his consumption of commodities s and t by x_s^h and x_t^h . Omitting the index h (for simplicity of presentation), the change

in his utility is

$$(5) \quad dv = v_s dP_s + v_t P_t \\ = -v_y (x_s dP_s + x_t dP_t)$$

where v_s is the derivative of $v(\cdot)$ with respect to P_s . The second equality is a result of Roy's identity. Substituting equation (4) into (5) we get

$$(6) \quad dv = -v_y [(x_s / X_s) - \alpha_{st} (x_t / X_t)] X_s dP_s.$$

Since v_y and X_s are positive and dP_s is negative, it is clear that individual h gains from the reform if the expression in brackets in (6) is positive. If this expression is nonnegative for all h , then the tax reform is a Pareto improving tax reform.⁸

A necessary condition, namely, that all additive concave social-welfare functions should show that the suggested reform is welfare-increasing, is that the reform does not worsen the utility of the poorest individual. (Otherwise a Rawlsian decision-maker will judge that the suggested reform decreases welfare.) The effect of the reform on the welfare of the poorest individual in the society can be seen by applying equation (6) to evaluate the change for this individual. The welfare of the poorest individual does not worsen if

$$(7) \quad (x_s^1 / X_s) - \alpha_{st} (x_t^1 / X_t)$$

is nonnegative. This expression is the difference between the poorest's individual's share of consumption of commodity s and

⁷To assume $\alpha_{st} < 0$ means that we are on the declining side of the Laffer curve. Alternatively, to require that α_s and α_t are both positive is to assume that an increase in the tax on each commodity increases tax revenue. Tatsuo Hatta and John Haltiwanger (1986) define such commodities as revenue-increasing commodities.

⁸The conditions for Pareto improving tax reforms are presented in Avinash Dixit (1975), Dixit and K. J. Munk (1977), Roger Guesnerie (1977), W. Erwin Diewert (1978), and Serge Wibaut (1987). The concept of a Pareto improving tax reform is more restrictive than the concept of first-degree stochastic dominance, because every individual must gain from the reform. Therefore, it must be based on efficiency gains. In contrast, our method is based on rules of second-degree stochastic dominance, which allow some individuals to lose due to the reform, provided that social welfare increases.

his share of commodity t multiplied by α_{st} . Hence, a necessary condition for all social-welfare functions to show an increase in social welfare is that the share of the expenditure of the poorest individual on commodity s should be higher than his share in the expenditure on commodity t multiplied by a constant.

Having established the condition for a socially acceptable reform with regard to the poorest individual, we next check the necessary condition applying to the poorest and next-to-poorest individuals together. By assumption, the marginal utility of income of the second individual is lower than the marginal utility of income of the first individual. Thus, another necessary condition is that the gain in real income for the first individual is higher than the loss, if any, for the second individual. By repeating the same considerations that led to (7), we obtain

$$(8) \quad [(x_s^1 + x_s^2)/X_s] - \alpha_{st}[(x_t^1 + x_t^2)/X_t] > 0.$$

The set of necessary conditions that applies to each group of individuals from 1 to N is thus

$$(9) \quad \left\{ \left[\sum_{h=1}^k x_s^h / X_s \right] - \alpha_{st} \left[\sum_{h=1}^k x_t^h / X_t \right] \right\} \geq 0$$

for $k = 1, \dots, N$.

Condition (9) has a straightforward interpretation. The expression in braces is the difference between the height of the relative concentration curve of commodity s and the height of the relative concentration curve of commodity t multiplied by a constant. The condition implies that for all additive social-welfare functions to show that this tax change increases social welfare it is necessary that the concentration curve of commodity s with respect to income is at least as high as the concentration curve of commodity t multiplied by a constant at each point of the income distribution. In Appendix A, it is shown that condition (9) is also sufficient for welfare dominance. We summarize the results in the following theorem.

THEOREM 1: *A necessary and sufficient condition for commodity s to dominate commodity t is that the concentration curve of s is at least as high as the concentration curve of t multiplied by α_{st} at each point of the income distribution.*

To explain this finding, it is instructive to construct what we refer to as the "difference in concentration curves" curve [hereafter the DCC(F) curve, where F is the cumulative distribution of income].⁹ The horizontal axis of this curve represents the cumulative distribution of income, while the vertical axis represents the difference between the concentration curve of commodity s and the concentration curve of commodity t multiplied by a constant, α_{st} . In other words, on the vertical axis we present the share of total expenditure on s minus α_{st} times the share of total expenditure on t for the poorest F families. Although all concentration curves start at (0,0) and end up at (1,1), all the DCC curves start at (0,0) and end up at $(0, 1 - \alpha_{st})$. The theorem states that, if the DCC(F) curve is everywhere above the horizontal axis, then s dominates t ; if it is entirely below the horizontal axis, then t dominates s . If the curve crosses the horizontal axis, neither s nor t dominates the other.

The DCC curve enables us to present in one figure both the efficiency gain from the reform and the way the gain is distributed among income groups. As shown in Yitzhaki and Wayne Thirsk (1990), the DCC curve describes the cumulative gain in real income for the poorest F households in society. The DCC curve is increasing (decreasing) if the individual at F gains (loses) from the reform.¹⁰ Since the curve reflects both ef-

⁹For simplicity of exposition, it is assumed that distributions are continuous. F denotes the cumulative distribution of the population, and its range is $[0,1]$.

¹⁰Note, however, that even if the DCC curve is increasing everywhere, it does not form a sufficient condition for a Pareto improving tax reform. If several individuals have the same income, the curve increases if the group (and not necessarily every individual in it) gains.

FIGURE 1. THE DCC CURVE

efficiency and distributive gains, it is convenient to separate the effects of these two causes.

The efficiency gains of a tax reform can be seen by concentrating on $DCC(1)$. At this point, the DCC curve describes whether the cumulative gain to the society is positive, zero, or negative. It is easy to see that $DCC(1)$ is larger (smaller) than 0 if and only if α_{st} is smaller (larger) than 1. In a one-consumer economy, the question of whether society gains from the reform collapses into whether $DCC(1)$ is greater than 0, or alternatively, whether α_{st} is less than 1. It can be shown that the condition $\alpha_{st} < 1$ is identical to the condition for a welfare-improving tax reform presented by Hatta and Haltiwanger (1986) in a one-consumer economy.¹¹ Therefore, we can interpret the condition $\alpha_{st} < 1$ as indicating whether the excess burden declines as a result of the reform. However, in a multiperson economy, a reform can be welfare-improving even if $\alpha_{st} = 1$,

the case in which there is no efficiency gain or loss. This can occur because the reform improves the distribution of welfare. In this case, the DCC curve will be above the horizontal axis, with $DCC(1) = 0$. If $DCC(1) < 0$ (i.e., $\alpha_{st} > 1$), then condition (9) cannot hold for all h , because it cannot hold for $h = N$. Thus, dominance is impossible. The intuitive explanation is that when $\alpha_{st} > 1$ the tax-policy change has increased the excess burden of the tax system. Therefore a decision-maker using a social-welfare function with (almost) constant marginal utility of income will oppose such a tax reform, which reduces the sum of all incomes. Thus, when $\alpha_{st} > 1$, agreement among all possible policymakers is impossible without further restricting the social-welfare function. If $\alpha_{st} < 1$, then a Pareto improving tax reform is possible. This would occur if the DCC curve increases everywhere, and every individual gains from the reform.

Distributive gains can be seen from the curvature of the DCC curve. If the DCC curve is increasing (decreasing), then the individual at that point of the income distribution is gaining (losing) from the reform, and the greater the slope, the larger the gain.

Figure 1 is an example of a DCC curve. The curve increases from 0 to F^* , which

¹¹It can be shown that the condition $\alpha_{st} < 1$ is identical to $N^{ab} > 0$ in lemma 1 of Hatta and Haltiwanger (1986 p. 307). They investigate the conditions under which $\alpha_{st} < 1$. If lump-sum taxes are available, then it is easy to see that $\alpha_{st} < 1$ is a sufficient condition for a Pareto improving tax reform. Appropriate lump-sum taxes ensure that the curve rises everywhere.

means that the lowest F^* individuals benefit from the reform, and it declines afterward, meaning that the top $1 - F^*$ individuals lose from the reform. The overall gain is equal to C .

Note that condition (9) does not constitute a complete ordering of revenue-neutral (commodity) tax changes. That is, if two concentration curves intersect, it will be impossible to find a small change in the taxation of the goods s and t such that all social-welfare functions can be judged to increase welfare. A complete ordering would require investigating the concentration curves further, to see whether restricting the class of social-welfare functions enables us to classify policies completely. This issue is discussed in the next section.

Although the ordering is not complete, it is clearly transitive: if commodity A dominates commodity B and commodity B dominates C, then A dominates C.¹² This property enables us to establish an ordering within the subgroup of commodities in which dominance is found.

Until now, we have been interested in an increase in the subsidy to one commodity, financed by an increase in the tax on another commodity. The same methodology can be used to ask whether an increase in a subsidy that is financed by a proportional income tax increases welfare. In this case, we treat total income as a commodity and look at the difference between the concentration curve for commodity s and the Lorenz curve. If the $DCC_{s,0}$ (where the index 0 indicates the Lorenz curve), is always positive, then commodity s dominates the proportional tax.

Finally, two important points are worth mentioning. As discussed above, concentration curves have often been used in the literature to describe the progressivity of taxes. However, the curves used in this pa-

per differ slightly from the standard use of concentration curves. In this paper, the curves are defined for after-tax income and are used to describe the progressivity of small changes in taxes. The reason for this modification is the following. In order to be consistent with welfare dominance, the ordering on the horizontal axis should be the ordering of the social evaluation of the utility of individuals. Since individuals with the same income may consume different quantities of commodities, changes in taxes may affect the ordering. The possibility of reordering which results in horizontal inequities restricts the use of concentration curves to cases involving small changes in taxes in order to indicate the preferred direction of the tax reform. In the case of a pure income tax, there is no problem of reordering, and therefore one can use Lorenz curves to order income taxes (see Roger Latham, 1988).

II. A Class of Easily Computable Necessary Conditions for Welfare Dominance

As noted above, the MCSD rules do not form a complete ordering across the taxable commodities. Moreover, we suspect that many commodities cannot be ordered by this method. In these cases, one may wish to investigate further restrictions on the set of possible welfare functions, such as rules of third-degree stochastic dominance.¹³ Applying such rules does not, however, ensure complete ordering in all cases. Therefore, their use may increase the set of commodities over which an ordering is defined, but it does not eliminate the problem of incomplete ordering.

¹²To see this, note that if the concentration curve of A is everywhere above the concentration curve of B, and the concentration curve of B is everywhere above the concentration curve of C, then it is clear that the concentration curve of A is everywhere above the concentration curve of C.

¹³For a definition of third-degree stochastic dominance, see G. A. Whitmore (1970). For an application in welfare economics, see Shorrocks and J. E. Foster (1987). It can be shown that a necessary and sufficient condition for third-degree marginal conditional stochastic dominance is that the area between the DCC curve and horizontal axis (i.e., the integral of DCC) is positive everywhere and that $DCC(1) > 0$. However, conditions of third-degree stochastic dominance are beyond the scope of this paper.

A procedure that does ensure complete ordering is to restrict ourselves to necessary conditions for welfare dominance. This is the case in which the analysis of tax reform is carried out using the Gini coefficient (Yitzhaki, 1987). This procedure provides a complete ordering that will never be rejected by any additive concave social-welfare function. It also is useful for making MCSD rules operational, because investigating the possibility of welfare dominance requires that $n(n-1)/2$ DCC curves be analyzed. As we show later, the use of necessary conditions decreases the number of curves that have to be investigated, and the procedure can be performed with a simple regression program.

The area below the 45° line minus the area below the concentration curve is defined as one-half of the concentration ratio. As shown in Yitzhaki and Olkin (1988), this area is also equal to

$$(10) \quad C_i = \text{Cov}[X_i, F(Y)] / m_i$$

where C_i is one-half of the concentration ratio, m_i is the mean expenditure on commodity i , and $F(Y)$ is the cumulative distribution of income. In other words, the concentration ratio is equal to twice the covariance between the expenditure on commodity i and the cumulative distribution of income divided by the mean expenditure on commodity i . Hence, the area between the concentration curve of commodity s and the concentration curve of commodity t (i.e., between the DCC_{st} curve and the horizontal axis) is¹⁴

$$(11) \quad C_s - \alpha_{st} C_t = \text{Cov}[X_s, F(Y)] / m_s \\ - \alpha_{st} \text{Cov}[X_t, F(Y)] / m_t.$$

By dividing and multiplying equation (11) by

$\text{Cov}[Y, F(Y)]$ and m_Y we can rewrite (11) as

$$(12) \quad \int_0^1 \text{DCC}_{st}(F) dF \\ = \{(b_s/S_s) - \alpha_{st}(b_t/S_t)\} G_Y$$

where G_Y is the Gini coefficient of income, S_i is the share of the expenditure on commodity i , and

$$(13) \quad b_i = \text{Cov}[X_i, F(Y)] / \text{Cov}[Y, F(Y)]$$

is a nonparametric estimator of the slope of the regression line of X_i on Y (Yitzhaki, 1987). In our context, b_i is a weighted mean of the marginal propensity to spend on commodity i . As argued in Yitzhaki (1987), b_i/S_i can be interpreted as the weighted average income elasticity of commodity i . Hence equation (12) tells us that the sign of the area below the DCC_{st} curve is determined by the difference between the weighted average income elasticities of the commodities. For commodity s to dominate commodity t , DCC_{st} must be positive; thus, it is clear that a necessary (but, of course, not sufficient) condition for welfare dominance is that the income elasticity of commodity s be lower than that of commodity t .

The use of the Gini coefficient means that we use a specific welfare function with a specific weighting scheme. However, one can use other weighting schemes. A family of weighting schemes that is based on the same argument is offered by the extended Gini (Yitzhaki, 1983). The extended Gini is a weighted integral of the area between the 45° line and the Lorenz curve. The formula for the extended Gini is

$$(14) \quad G(\nu) = -\nu \text{Cov}\{Y, [1 - F(Y)]^{\nu-1}\} / m_Y \\ \nu > 1$$

where ν is a parameter chosen by the investigator. The extended Gini is similar to the Gini coefficient but uses a different weighting scheme. The Gini is a special case of the extended Gini, where ν is 2. The higher is

¹⁴The derivation of this equation and that of equation (15) appear in Appendix B.

ν , the greater is the emphasis on the bottom of the income distribution.¹⁵

The above analysis using the Gini can be carried out using the extended Gini. In Appendix B, we show that a decrease in the consumer price of commodity s , financed by an increase in the consumer price of commodity t , decreases the extended Gini inequality index, if

(15)

$$\int_0^1 [\Theta_s(F) - \alpha_{st}\Theta_t(F)](1-F)^{\nu-2} dF > 0$$

where $\Theta(F)$ is the concentration curve. Since $\Theta_s - \alpha_{st}\Theta_t$ is the DCC_{st} curve, the analysis of tax reform with the extended Gini coefficient provides additional necessary conditions for welfare dominance. If commodity s dominates commodity t , then a shift from taxing commodity s to commodity t must decrease the extended Gini inequality index for all ν , including the standard Gini case where $\nu = 2$. These necessary conditions are useful in the empirical investigation of welfare dominance because they are fairly easy to calculate (see Robert Lerman and Yitzhaki, 1989) and can be used to identify those pairs of commodities for which welfare dominance is possible.

III. An Illustration with Israeli Data

This section illustrates the methodology of welfare dominance using cross-sectional data on the consumption of subsidized commodities in Israel. The data set is the Survey of Family Expenditure (1979/1980) conducted by the Israel Central Bureau of Statistics. This survey consists of a random stratified sample of 2,271 urban households. Since we are interested in the level of economic well-being, the concept of income per standard adult is used.¹⁶ The households

are ordered according to net total income per standard adult, where net total income is defined as monetary income plus imputed income from ownership of housing and vehicles minus income and social security taxes.¹⁷

Before presenting the results, two technical points are worth making. In general, if there are n commodities, one would have to plot $n(n-1)/2$ pairs of concentration curves to investigate the existence of welfare dominance. Since cross-sectional samples usually contain thousands of observations, this can clearly become a cumbersome procedure when more than a few commodities are being studied. As suggested above, comparisons of the magnitude of the weighted income elasticities, according to the Gini or extended Gini coefficient, yield necessary conditions for dominance, thus reducing the number of comparisons of curves needed. The second issue arises because of the use of a sample instead of the whole population. As shown by Charles Goldie (1977), sample-based Lorenz curves do converge to the population Lorenz curve, but it is clear that our results may be affected by the sample variability. One way to reduce the sample variability is to average observations. However, some information is lost by averaging. Hence, in what follows we plot concentration curves based on the whole sample and also report the results when concentration curves are based on averaging consecutive pairs of observations. We assume that $\alpha_{st} = 1$, implying that reform neither increases nor decreases the excess burden.

size of the household on consumption needs. The scale that is used is the following: single = 1.25 standard adults; a couple without children = 2.0; a couple with one child = 2.65; with two children = 3.2; with three children = 3.75; with four children = 4.2; and 0.4 for each additional child. This scale is used in many official publications of the National Insurance Institute and the Central Bureau of Statistics in Israel.

¹⁵See Yitzhaki (1983) for a discussion of the properties of the extended Gini. See Wilhelm Pfähler (1987) for a discussion of a general class of progressivity measures.

¹⁶The concept of a standard adult is an equivalence scale intended to take into account the effect of the

¹⁷The sample is a stratified one, which means that each household in the sample represents a different number of households in the population. The equations given in this paper have therefore been adjusted in a straightforward manner to account for this (see Lerman and Yitzhaki, 1989).

TABLE 1—INCOME ELASTICITIES OF SEVERAL SUBSIDIZED COMMODITIES
IN ISRAEL DURING 1979/1980

Gini parameter	$\nu = 1.5$	$\nu = 2$	$\nu = 4$
Cooking oil	-0.13	-0.14	-0.11
Bread	-0.06	-0.07	-0.09
Sugar	0.07	0.06	0.08
Public transportation	0.12	0.15	0.25
Water for household consumption	0.31	0.30	0.33

Source: Authors' calculations from The Survey of Family Expenditure 1979/1980, Central Bureau of Statistics, Israel.

Table 1 presents weighted average income elasticities, estimated by using several variants of the extended Gini coefficient. As can be seen, there are two inferior commodities (bread and cooking oil), while the other commodities are normal.

As mentioned above, the higher is ν the greater is the weight given to the lower portion of the income distribution. Hence, we can conclude from the table that the income elasticity of public transportation declines as income increases, while bread tends to be less inferior the higher the income level. Since the income elasticity of cooking oil is lower than the income elasticity of bread for all the values of ν we studied, the necessary conditions for cooking oil to dominate bread are met, and it is reasonable to check whether cooking oil dominates bread. By the same reasoning, we conclude from Table 1 that, if there is dominance, the ordering must be: cooking oil, bread, sugar, public transportation, and finally water for household consumption. It is impossible that a good will be dominated by another good lower in the table.

Figure 2 presents the curve of the difference between the concentration curves (DCC curve) of cooking oil and bread. As expected from Table 1, the area above 0 on the x-axis is larger than the area below it. (The difference between the areas is equal to the income elasticity of cooking oil minus that of bread calculated by the Gini index.) Hence, we can see that cooking oil is more inferior than bread when the weighting

scheme of the Gini is used. However, the curve intersects 0 on the x-axis, implying that for the lower two deciles of the income distribution bread has a lower income elasticity than cooking oil, while for the other deciles bread has a higher income elasticity. If the social-welfare function is concave only for the lower two deciles, then taxation policy should shift to subsidize bread at the expense of cooking oil. The conclusion is that cooking oil does not dominate bread.

Figure 3 presents the DCC curve between bread and water for household consumption. As can be seen, the curve is always above 0 on the x-axis, and hence bread dominates water.¹⁸ A small increase in the tax on water that finances a small increase in the subsidy to bread will be welfare-improving for all concave social-welfare functions.

¹⁸ A close examination of the individual observations reveals that the curve intersects the x-axis for the very last observation, so that the share of the richest household in the sample in total expenditure on bread is higher than its share in the overall expenditure on water. If this sample exactly portrayed the population, a social-welfare function that is linear over the whole range of the distribution and concave between the second-richest family and the richest one would show that subsidizing bread at the expense of water would be welfare-decreasing. However, we suspect that this is a result of a sampling error. If we take the average of two consecutive observations, this proviso disappears. Note, however, that the question of sampling variability is not addressed.

FIGURE 2. THE DIFFERENCE BETWEEN CONCENTRATION CURVES OF OIL AND BREAD

FIGURE 3. THE DIFFERENCE BETWEEN CONCENTRATION CURVES OF BREAD AND WATER

Figure 4 presents the DCC of bread and public transportation. Except for one observation, bread dominates public transportation. If we plot the DCC averaging every two consecutive observations, then bread dominates public transportation with no exceptions. This phenomenon illustrates just

how strong the condition of MCSD is. Even if the entire population is studied, the consumption patterns of the poorest and the richest members of society are critical in determining the existence of dominance.

Figure 5 presents the DCC of bread minus the Lorenz curve. This figure is in-

FIGURE 4. THE DIFFERENCE BETWEEN CONCENTRATION CURVES OF BREAD AND PUBLIC TRANSPORTATION

FIGURE 5. THE DIFFERENCE BETWEEN THE CONCENTRATION CURVE OF BREAD AND THE LORENZ CURVE

tended to show whether an increase in the subsidy on bread, financed by an increase in a proportional income tax, increases welfare for all additive concave Paretian social-welfare functions. Because the DCC curve is above 0 on the x-axis over the entire income range, the answer to this question is yes.

IV. Conclusions

Because the exact properties of social-welfare functions are not known and are likely to remain so, it would be valuable to make judgments about potential tax reforms that depend only on relatively noncontroversial characteristics of the social-welfare

function. The methodology provided in this paper is a step in this direction. It derives the conditions (called marginal conditional stochastic dominance rules) that must hold for all individuals with additive Paretian concave social-welfare functions to agree that an increase in the subsidy on one commodity, financed by an increase in the tax on another commodity (or a proportional income tax), increases social welfare. If this reform does not increase the excess burden, then all individuals will agree on the preferred direction of tax reform. An inspection of Israeli data suggests that these conditions are quite commonly observed in practice.

One direction for future research is to apply this methodology to a weighted combination of commodities. In this case, a set of changes in taxes and subsidies can be compared to another set in order to see whether all individuals can agree on the welfare implications of a particular tax reform. In the present setting of MCSD rules, the permissible set of welfare functions includes welfare functions that are almost linear (constant marginal utility). The permissibility of such welfare functions means that it will be impossible to find unanimous preference for any redistribution that increases efficiency costs. Therefore, only by limiting the set of the admissible welfare functions will it be possible to find MCSD rules for costly redistribution. One possible way of doing this is to restrict the set such that only welfare functions with some minimum concavity are included.

APPENDIX A

In this appendix, we prove that if the concentration curve of s is at least as high as the concentration curve of t times α_{st} , then it is impossible to find a welfare function that shows that subsidizing t (and taxing s) increases welfare.

Formally, if

$$(9) \quad \left\{ \left[\sum_{h=1}^k x_s^h / X_s \right] - \alpha_{st} \left[\sum_{h=1}^k x_t^h / X_t \right] \right\} \geq 0$$

for all k

or, in its continuous version,

(A1)

$$\int_0^y [(x_s(z)/X_s) - \alpha_{st}(x_t(z)/X_t)] f(z) dz \geq 0$$

for all y

where $f(z)$ is the density function, then it is impossible to find a welfare function that shows that decreasing the price of t and increasing the price of s while keeping revenue constant increases welfare.

To prove this assertion, we first assume that such a welfare function exists. Then,

$$(A2) \quad \int w_v(v_s dP_s + v_t dP_t) f(y) dy > 0$$

where $w_v = \partial w / \partial v > 0$. Using Roy's identity and (4), we find that (A2) is equal to

$$(A3) \quad \int -\beta(y) [x_s(y) dP_s + x_t(y) dP_t] f(y) dy$$

$$= -dP_s \int \beta(y) [(x_s(y)/X_s) - \alpha_{st}(x_t(y)/X_t)] f(y) dy \geq 0$$

where $\beta(y) = w_v v_y$ is the marginal welfare. Since dP_s is positive, the integral is nonpositive. Since $\beta(y)$ is nonnegative and nonincreasing with y , we can use the following lemma from Yitzhaki (1982 p. 179), which completes the proof.

LEMMA: Let $V_y(y)$ be a nonnegative and nonincreasing function and let $B(y)$ be a function with the following property: $\int_0^y B(z) dz \geq 0$ for all y . Then $\int_0^y V_y(z) B(z) dz \geq 0$ for all y .

Now, if one lets $B(z) = [(x_s(z)/X_s) - \alpha_{st}(x_t(z)/X_t)] f(z)$, then by (A1) the requirements for the lemma are fulfilled. Hence, (A3) is contradicted.

APPENDIX B

In this appendix we prove the following results:

- (a) the derivative of the extended Gini of overall income with respect to equal-revenue tax changes is equal to the difference in the (weighted) concentration ratio of the commodities involved in the tax changes;
- (b) the (weighted) concentration ratio is equal to the (weighted) area between the 45° line and the concentration curve.

Properties (a) and (b) together with equation (4) ensure that a necessary condition for one commodity to dominate another is that the extended Gini of inequality declines as a result of the changes in taxes.

PROOF OF PROPERTY (a):

For simplicity of presentation, we assume that the distributions are continuous and that only two commodities are involved. Let

$$(B1) \quad y = P_1 x_1 + P_2 x_2$$

where $P_i = 1$ is the price of commodity i , y denotes income, and x represents commodities. The extended Gini inequality index is

$$(B2)$$

$$G_y(\nu) = -\nu \text{Cov}(y, [1 - F(y)]^{\nu-1}) / m_y$$

where m denotes the mean.

The derivative of $G_y(\nu)$ with respect to P_1 , evaluated at $P_1 = 1$, can be interpreted as the effect of a change in the tax on commodity 1 on the extended Gini. Note that P_1 affects both the numerator and the denominator of (B2). Let us start with the derivative of the numerator.

Let $A(y) = 1 - F(y)$. Note that

$$E_y[A^{\nu-1}(y)] = \int_0^\infty [1 - F(y)]^{\nu-1} f(y) dy$$

and by transformation of variables with $F =$

$F(y)$ we get

$$(B3) \quad E_y[A^{\nu-1}(y)] = \int_0^1 (1 - F)^{\nu-1} dF = 1/\nu.$$

Using (B3), the numerator of (B2) can be written as

$$\text{Cov}[y, A^{\nu-1}(y)] = \int_0^\infty y[\nu A^{\nu-1}(y) - 1] f(y) dy$$

and again using the same transformation of variables where $F = F(y)$

$$(B4) \quad \text{Cov}[y, A^{\nu-1}(y)] = \int_0^1 y(F) [\nu(1 - F)^{\nu-1} - 1] dF$$

where $y(F) = \inf\{y | F(y) > F\}$ is the inverse of the cumulative distribution. Differentiating (B4) while using (B1) yields

$$(B5) \quad \partial \text{Cov}[y, A^{\nu-1}(y)] / \partial p_1 = \int_0^1 x_1(F) [\nu(1 - F)^{\nu-1} - 1] dF$$

and, by reversing the procedure that led from (B2) to (B4), we get

$$(B6) \quad \partial \text{Cov}[y, A^{\nu-1}(y)] / \partial p_1 = \text{Cov}\{x_1, [1 - F(y)]^{\nu-1}\}.$$

Now that the derivative of the numerator is known, we can derive the derivative of the extended Gini with respect to p_1 .

$$(B7) \quad \partial G_y(\nu) / \partial p_1 = S_1 c(x_1, y, \nu) - S_1 G_y(\nu)$$

where $S_1 = m_1 / m_y$ is the share of x_1 and $c(x_1, y, \nu) = -\nu \text{Cov}\{x_1, [1 - F(y)]^{\nu-1}\} / m_1$ is the (weighted) concentration index.

The effect of an equal-revenue tax change on the extended Gini can be evaluated by using (B7). Let dG/dR denote the derivative of the extended Gini with respect to a tax reform; that is,

$$(B8) \quad dG/dR = [\partial G_y(\nu)/\partial p_1] dp_1 + [\partial G_y(\nu)/\partial p_2] dp_2.$$

By using the equal-yield revenue restriction, $m_1 \alpha_1 dp_1 + m_2 \alpha_2 dp_2 = 0$, and (B7) we get

$$(B9) \quad dG/dR = [c(x_1, y, \nu) - \alpha_{12} c(x_2, y, \nu)] S_1 dp_1$$

which means that the effect of the tax reform on the extended Gini depends on the difference between the concentration ratios of the commodities and the deadweight loss of the tax system. Note that we assumed $\alpha_{12} = 1$; that is, the change in the deadweight loss is zero. This completes the proof of property (a).

PROOF OF PROPERTY (b):

Let x represent the expenditure on a commodity; then, the (extended Gini) concentration ratio is defined as

$$(B10) \quad c(x, y, \nu) = -\nu \text{Cov}\{x, [1 - F(y)]^{\nu-1}\} / m_x.$$

Writing the covariance explicitly and eliminating zeros yields

$$(B11) \quad c(x, y, \nu) = -(\nu/m_x) E_y E_x \{ (x - m_x) [1 - F(y)]^{\nu-1} \}.$$

Now let $g(y) = E_x(x|y)$, so that $g(y)$ is the Engel curve. Then (B11) can be written as

$$(B12) \quad c(x, y, \nu) = (-\nu/m_x) \times \int_0^\infty [g(y) - m_x] [1 - F(y)]^{\nu-1} f(y) dy$$

and by integration by parts, where

$$V(y) = [1 - F(y)]^{\nu-1} \\ U'(y) = [g(y) - m_x] f(y)$$

and by rearranging terms, we get

$$(B13) \quad c(x, y, \nu) = [-\nu(\nu-1)/m_x] \\ \times \int_0^\infty \int_0^y [g(t) - m_x] f(t) dt \\ \times [1 - F(y)]^{\nu-2} f(y) dy.$$

By transformation of variables, where $F = F(y)$ and

$$\Theta_x(F) = (1/m_x) \int_0^F g(y(F)) dF$$

is the concentration curve, we get

$$(B14) \quad c(x, y, \nu) = -\nu(\nu-1) \\ \times \int_0^1 [\Theta_x(F) - F] [1 - F]^{\nu-2} dF$$

which means that in the case of the Gini ($\nu = 2$) the concentration ratio is equal to twice the area between the concentration curve and the 45° line. In other cases, the (extended) Gini concentration ratio is equal to a (weighted) difference of the area between the 45° line and the concentration curve. Note that the difference between concentration ratios is hence equal to the (weighted) difference between concentration curves.

The Role of Demandable Debt in Structuring Optimal Banking Arrangements

By CHARLES W. CALOMIRIS AND CHARLES M. KAHN*

Demandable-debt finance by banks warrants explanation because it entails costs of bank suspension, liquidation, and idle reserve holdings. An explanation is developed in which demandable debt provides incentive-compatible intermediation where the banker has comparative advantage in allocating investment funds but may act against the interests of uninformed depositors. Demandable debt attracts funds by giving depositors an option to force liquidation. Its usefulness in transacting follows from information-sharing between monitors and nonmonitors. (JEL G21)

For centuries, the vast majority of externally financed investments have been funded by banks, for which demandable-debt instruments (bank notes and checking accounts) have been the principal source of funds. The goal of this paper is to explain the emergence of demandable-debt banking historically as the primary means of external finance in the economy.

Demandable debt warrants explanation because, in several respects, it appears more costly than available alternative contracting structures. By issuing demandable debt, banks created a mismatch between the maturity of assets and liabilities. This mismatch left them exposed to the possibility that depositors would attempt to withdraw more

funds than a bank could supply on short notice. When this occurred, the consequences were costly. Individual banks that did not meet their obligations were forced into expensive procedures (liquidation or receivership) that would not have arisen in an equity-based or maturity-matched contracting structure.¹ If depositors en masse attempted to withdraw funds from the entire banking system, banks as a group were forced to suspend convertibility of their liabilities into specie on demand. Such suspension was also disruptive and costly. To defend against either of these undesirable consequences, banks had to hold a proportion of their assets in idle reserves to insulate themselves from excessive withdrawals.

Given these costs, demandable debt seems inferior to both maturity-matched debt and equity contracting. However, in this paper, we show that demandable debt has an important advantage as part of an incentive scheme for disciplining the banker. In effect, demandable debt permits depositors to "vote with their feet"; withdrawal of funds is a vote of no-confidence in the activities of the banker. Without the ability to make early withdrawals, depositors would have little incentive to monitor the bank.

Prochnow Educational Foundation of the Graduate School of Banking, Madison, WI, for additional support.

¹Kenneth R. Cone (1983) shows that, in a world of full information, the risk of depositor liquidation under demandable debt is absent, provided that financial intermediaries are maturity-matched.

This account gives a natural rationale for two important institutional features of banking. The so-called "sequential service constraint," by which payments were made to demanders on a first-come, first-served basis, becomes intelligible as a way to make monitoring depositors interested in registering their no-confidence votes at the first opportunity. The ease with which banks may be forced into liquidation, far from being an unfortunate consequence of the contracting structure, turns out to be central to the structure: we show that, by submitting to the threat of liquidation under appropriate circumstances, the banker can reduce his cost of capital.

In addition, our account may have wider applicability. Features of modern capital structures of nonfinancial institutions bear important similarities to the historical role of demandable debt. Modern-day firms often have multilayered debt structures, in which certain debt-holders have priority of claim for repayment. Claimants to short-term senior debt in modern firms may play a similar role to that of the monitoring depositors in our model.

The paper is organized as follows: In Section I, we contrast our explanation of demandable debt with the literature based on desire for flexibility of consumption. The model in Section II demonstrates the value of a demandable-debt contract in the case of a single investor contracting with the banker monopolist. Here, a run corresponds to a demand by the investor for liquidation of the bank. Section III examines the case in which different monitors receive different (independent and identically distributed) signals. In this case, it pays to have more than one depositor monitoring the bank, because the quality of signals in the aggregate improves with the number of monitors. Banks find it advantageous to hold reserves to provide a buffer that reduces the likelihood of unwarranted liquidation. An optimal threshold of withdrawal orders is chosen at which the bank is liquidated, and relative payoffs ensure that the optimal number of monitors invest in receiving signals.

At the end of Section III, we briefly and informally indicate how solving the incentive problem facing the banker will also make the banker's liabilities more transactable. Formal models combining the incentive problem and liquidity are an important field for further research.² Section IV summarizes and indicates important limitations of our results.

I. Explanations for Demandable Debt

Recent theoretical work on the role of banks has tended to divide into two categories. Theory in one category emphasizes the role of banks as providing flexibility for depositors in the timing of consumption. Theory in the other category, to which our paper belongs, emphasizes the *incentive* problem inherent in the divergence of interest between a bank's depositors and its managers.³ For reasons indicated below, we believe that accounts which ignore the incentive problem facing the banker do not adequately explain why banks historically settled on demandable debt.

A. Consumption Flexibility and Demandable Debt

In the past several years, the preeminent theoretical analyses of banks, bank runs, and bank regulation have assumed that the economic role of demandable debt is to provide flexibility to risk-averse depositors who are uncertain about the timing of their future consumption demand.⁴ In this category of models, bank runs, when they occur, are an unfortunate and undesirable side-

²See Gary Gorton and George Pennacchi (1988), Charles J. Jacklin (1988), and A. P. Villamil (1988) for various approaches to combining the liquidity and incentive arguments.

³Jacklin and Sudipto Bhattacharya (1988) give a concise but useful review of these approaches.

⁴Fundamental papers that utilize this approach are by John Bryant (1980), Douglas W. Diamond and Philip Dybvig (1983), and Jacklin (1987). For a model emphasizing the costs to depositors of delay in liquidation, see Merwan Engineer (1987).

effect of a contract whose whole purpose is to provide consumption flexibility.

Although these models provide both a concise formalization of the fact that banks provide consumption flexibility and a coherent account of bank runs, they are unable to account for several important institutional features of demandable debt. First, in the absence of incentive constraints on the part of the banker, the optimal arrangement in liquidity-based accounts always involves suspension of convertibility, rather than expensive liquidation. However, suspension was not an option available to individual banks; it was only an alternative for the financial system as a whole, in the face of system-wide panics. Individual banks that could not satisfy creditors' fears about solvency were not permitted to suspend; they were forced to close.⁵

Second, studies of actual bank failures give fraud a prominent place in the list of causes. Studies of 19th- and 20th-century banking indicate that fraud and conflicts of interest characterize the vast majority of bank failures for state and nationally chartered banks.⁶

⁵See Calomiris and Larry Schweikart (1988) for a discussion of suspension rules during the early U.S. experience. Kevin Dowd (1988) argues that individual-bank suspension of debt redemption would have been beneficial but was prevented by legal prohibitions. We argue that the prohibition-of-suspension option clauses simply reflected the learned desirability of placing the decision regarding whether suspension was "justified" outside the control of the individual banker. The legal prohibition of option clauses on notes may have been perceived as necessary to protect some unsophisticated note-holders, while no such law was deemed necessary for relatively sophisticated depositors.

⁶For example, E. L. Smead (1928) found that three of the nine most common causes of bank failure in the 1920's involved fraudulent or questionable activities by the banker: loans to officers and directors, outright defalcation, and loans to enterprises in which officers and directors were interested. For discussions of the role of fraud in earlier eras, see Carter H. Golembe and Clark Warburton (1958), George J. Bentson and George G. Kaufman (1986), and Calomiris and Schweikart (1988). Data on national bank failures, by cause, can be found in the Annual Report of the Comptroller of the Currency (1920 pp. 56-79). For information on the importance of fraud in more recent bank failures, see Comptroller of the Currency (1988).

Third, receivership resulted from a critical mass of depositor withdrawal orders and was invoked because of information about bank asset values, not because of exogenous liquidity needs of individual depositors. In cases of massive exogenous demand for an individual bank's assets by small depositors, banks avoided failure by appealing to other banks for loans of reserves; however, when large informed depositors (including other bankers) concluded that a bank was in trouble, they would precipitate a run, depleting the bank's reserves and forcing it to be placed in receivership.⁷

These considerations make it apparent that the liquidation of banks—which was part and parcel of demandable-debt contracts—was designed to place the assets of banks beyond the reach of the banker. The rationale for prohibiting banks from suspending at their own discretion may have been the discipline that it imposed on the behavior of the banker. Thus, a model of demandable debt with bank liquidation through receivership should account for the desirability of taking control of the bank away from the banker at the option of depositors.

Fourth, the "sequential-service constraint" (first-come, first-served rule) for bank withdrawals, which allowed informed depositors to receive repayment before banks were placed into receivership, also

⁷Henry C. Nicholas (1907 p. 26) dismissed the importance of withdrawals by uninformed depositors in causing bank liquidation. He wrote, "If a bank is actually in bad shape there is far more likelihood of its initial condition being discovered by other banking institutions than by the individual depositors of the bank A run is sometimes started in this manner ... and continues until it has practically wiped out the reserves of the suspected institution, the ordinary depositors receiving their first information regarding the position of the bank when that institution is finally forced to close its doors and formally apply for a receiver." This discussion makes important points about bank runs which appear in our model: some depositors are informed, while others are not. Runs by informed depositors end in liquidation. Informed depositors are able to exercise their withdrawal option before uninformed depositors are able to observe the bank's difficulty (or the run).

warrants explanation. In cases other than banking, payments from bankrupt firms to creditors in anticipation of bankruptcy are not allowed, and creditors may be forced to relinquish such payments during the bankruptcy proceeding. Why in the case of banking should those who run the bank receive preferential treatment in liquidation states?

B. Demandable Debt as an Incentive Scheme

Models in the second category of theory on the role of banks begin with the assumption that bankers have an informational advantage in determining which projects are most worthy of financing. Therefore, the banker has a comparative advantage in allocating funds for investment, but he also may have the ability to act against the interests of uninformed depositors.⁸

We show that demandable debt can provide an incentive-compatible solution to this problem in the presence of costly information. The right to take one's money out of the bank if one becomes suspicious that realized returns are low makes it in the depositor's interest to keep an eye on the bank. If enough depositors agree with this negative assessment of the bank's future, liquidation will be called for, and the bank

will close. The demandable-debt contract allows the banker to precommit to a set of payoffs he otherwise would not be able to offer depositors.

Not all depositors need monitor the banker. We argue that the first-come, first-served (sequential service) rule of demandable debt provides compensation for those who choose to invest in information and thus avoids free-riding. We view bank intermediation, therefore, as a three-sided relationship. The monitors pay the costs of vigilance but receive the benefit of knowing that they will be "first in line" (and thereby receive a higher payment than other depositors) should it become necessary to withdraw their funds from the bank. The depositors who do not monitor are willing to pay the price of being last in line in "bad" states, because they receive a benefit in return: the active monitors keep the banker in line and thereby provide a benefit to the passive depositors. Depositors need not reveal whether they are active or passive; the same contract works for both types.

The physical structure we assume includes the following important features. 1) The bank is operated by a monopolist with special access to a profitable investment opportunity which yields either a good or a bad realization. 2) There is potential for cheating by the banker which takes the form of his absconding with a proportion of the bank's assets after the investment realization. (One can think of this more generally as costly *ex post* fraudulent behavior which the banker undertakes whenever it is more profitable to do so than to make the promised payments to depositors.) 3) Depositors face different costs of obtaining a signal that allows them to predict profitability. 4) An authority exists who will enforce contracts (some of which may stipulate conditions for bank liquidation) and who can act as receiver for liquidated banks. 5) Depositors have a reservation level of return on their endowments below which they will not invest funds with the banker.

The profit-maximizing banker will act to maximize social gain by selecting a contract that achieves beneficial intermediation (investment in profitable enterprises), while

⁸This point is emphasized by Diamond (1984) and Ben Bernanke and Mark Gertler (1987). For an overview of the relation between agency costs and the structure of financial contracts, see Eugene F. Fama (1988). Diamond's solution to the delegated-monitoring problem of financial intermediation relies on two assumptions that are absent in our framework: the existence of an *ex post* nonpecuniary penalty that can be imposed on the banker and the ability of the banker to construct a riskless portfolio through diversification. The second assumption permits enforcement of the penalty, even if cheating is costly to observe directly, whenever the banker fails to meet his obligations. Bernanke and Gertler provide a simple macroeconomic model in which bankers are subject to moral hazard and depositors desire liquidity. They explicitly assume that costly monitoring and punishment of defaulting bankers are not possible. For them, demandable debt is desirable solely for its liquidity. In our model, demandable debt is desirable although liquidity demand is absent.

avoiding as much as possible the costs associated with absconding or liquidating. We find that the demandable-debt contract is optimal for a range of parameter values. The potential for costly liquidation may be more than offset by the social gain that comes from enhanced investment opportunities.⁹

II. The Model with a Single Depositor

A. Physical Structure

A banker has an investment opportunity, but he lacks sufficient capital to take advantage of it. The investment opportunity costs one dollar. Each potential depositor has one dollar to invest. We will let S represent the total expected return available for a dollar's investment elsewhere in the economy. We assume that all agents are risk-neutral; thus, any scheme the banker develops will have to yield a depositor that same expected return.

The investment opportunity yields an uncertain payoff which may take one of two values, T_1 or T_2 , with $T_2 > T_1$. The probabil-

ity of the high outcome is γ . The realization is unknown to all parties at the outset and is observable *ex post* only by the banker. Thus, there is no way to make a contract tied directly to the value of T_i .¹⁰

Let period 3 be the date at which the payoff is realized and the loan is to be repaid. We assume that in period 3, immediately before repayment, the banker has the opportunity to abscond with the funds. Absconding is socially wasteful; for concreteness, we will assume that it reduces the realization T_i by the proportion A , where A is between 0 and 1.

Although the act of absconding reduces the size of the pie that is divided between the banker and the depositor, it places the banker beyond the reach of the law. Therefore, he is no longer constrained to repay the loan as initially promised. Thus, any promise to pay the depositor an amount P is actually an option of the banker either to pay P or to leave town with his assets diminished by the proportion A .

The losses from absconding may be interpreted in a variety of ways. They may represent the cost of engaging in fraud (payments to coconspirators) or the costs (forgone earnings) of placing the bank's resources in a form that allows theft. The latter interpretation requires a richer, multiperiod model than the one we provide, in which bankers' allocation decisions depend on last-period earnings.¹¹

It should be readily apparent that the temptation to abscond will be greater with lower realizations of T_i . In deciding whether

⁹V. Chari and Ravi Jagannathan (1988) provide an example of an information-based run for a model that has many features in common with ours. A key difference is that they assume an (exogeneously imposed) negative externality from liquidation of the bank's assets. In their model, the creation of a liquidation technology is not efficient. In our model, there is a positive externality from running the bank: when the depositor observes a bad signal, he calls for liquidation, thereby salvaging some of the bank's value. The bank's structure is designed to internalize this positive externality and allows nonmonitoring depositors to compensate monitors for the benefits they provide.

Our model can also be interpreted as allowing depositors to exercise a put option based on the information they receive. However, unlike the usual "inside-trading" scenario, the uninformed depositors also benefit at the expense of the bank. While the uninformed depositors receive a lower payoff than the informed depositors, they benefit because the bank is prevented from cheating. In the usual scenario (e.g., Albert S. Kyle, 1981), the uninformed either lose or the informed cannot successfully earn a return on their information-production because of free-riding, as in Sanford J. Grossman and Joseph E. Stiglitz (1980). We thank an anonymous referee for suggesting this comparison to us.

¹⁰We assume that the banker is not able to trade in equity shares. This conforms with the relative illiquidity of equity trade in the period under examination. It could also be generated as a conclusion in a model in which bankers possess specialized information about investment projects of borrowers. Robert M. Townsend (1979) notes that in circumstances when only one party has access to information, debt contracts (i.e., contracts not contingent on the private information) will often be the only feasible alternative.

¹¹The plausibility of our "leaky bucket" assumption and possible multiperiod reinterpretations are discussed further in the final section of the paper. For an initial generalization of the absconding assumption see Calomiris et al. (1990).

to abscond, the banker compares the "tax" on absconding, AT_1 , with the promised funds due the depositor. If the absconding tax is less, then absconding is more profitable than paying up. Historical evidence confirms the greater prevalence of fraud in times of low returns to bank investments.¹²

Because of the threat that the banker will abscond—a threat against which he cannot commit himself—it will generally be necessary for the banker to increase the payment offered to a depositor by a "default premium" as protection against those states in which the depositor will, in fact, receive nothing.

Note that the addition of a default premium can, in turn, increase the probability of default, by making it desirable for the banker to abscond in good states as well. For example, suppose

$$S > AT_1$$

so that any payment promised to the depositor must be sufficiently large to incur absconding in the low realization; that is, a promise to pay P will only be honored a fraction γ of the time. Suppose also that

$$\gamma T_2 + (1 - \gamma)(1 - A)T_1 > S$$

so that the investment would be socially desirable (even taking into account the loss from absconding in the low realization). Then, if

$$S > \gamma AT_2$$

there is no way to promise the depositor enough expected payment to make him willing to invest, despite the social desirability of the project; the promised payment would have to exceed AT_2 , making it desirable for the banker to abscond all the time.

¹²The concentration of bank fraud during times of regional or national economic decline is pronounced in national bank-failure data. See the Annual Report of the U.S. Comptroller of the Currency (1920 pp. 56–79).

Because of the loss of socially desirable opportunities, it is useful to have a method of thwarting absconding. One such method is the liquidation of the bank in period 2. Liquidation means that the bank's assets are taken over by a receiver, controlled by a court. This is an expensive process, not the least because the court-appointed and court-controlled receiver is likely to be less able to realize the full potential of the assets. On the other hand, the fact that the assets are no longer in the banker's control preempts any decision by him to abscond with the funds.

We assume that liquidation reduces the value of the assets by the proportion L , so that L can be regarded as the tax due to liquidation. For a complete characterization of the process of liquidation, it is necessary to take some stand as to the maximum that can be feasibly paid to the depositor in the case of liquidation. We call this value M , and we assume that¹³

$$(1) \quad AT_2 > M > AT_1$$

so that the amount that can be guaranteed to the depositor in a liquidating contract is greater than the maximum amount that can be guaranteed in a nonliquidating contract. We also assume that

$$(2) \quad L > A$$

so that liquidation is less wasteful socially than is absconding.¹⁴

¹³There are several ways we can approach the question of the maximum to be paid once the court has control. For simplicity, we assume that M does not vary with the realization of T_1 . One argument is that the value of the firm might be determined by the court, but at a very high cost.

¹⁴Actual liquidation costs in the United States varied historically, depending on time, location, and bank size but seem to have been small relative to potential social losses from absconding, as our model assumes. Bankruptcy expenses averaged between three percent and six percent of total collections for national banks between 1872 and 1904 (Brian C. Gendreau and Scott S. Prince, 1986).

In some cases, it may be desirable *always* to put the assets of the bank into liquidation rather than risk the banker's absconding. We call such an agreement a "simple liquidation contract," as opposed to a "simple nonliquidation contract," which states a promised repayment and leaves it to the banker whether to abscond or not.

The more interesting case, however, is one in which the depositor, based on his own information, is given the option of demanding liquidation or not. Specifically, suppose that by paying a cost I the depositor is able to receive a signal σ in period 1 as to the likelihood of a high (T_2) or low (T_1) realization. The action of investing in the signal and the result of this action are private. The signal σ works as follows. It takes on one of two values $\{g, b\}$ (for "good" and "bad").¹⁵ The probability of a high realization, contingent on the signal, is ρ_σ :

$$(3) \quad \rho_g > \gamma > \rho_b.$$

We will use the indicator variable $e \in \{0, 1\}$ to represent the depositor's choice: $e = 1$ if there was an investment in the signal, 0 otherwise.

In summary, the physical structure of our model is as follows. There are three periods. In period 1, the depositor may invest in receiving a signal. In period 2, the bank may be liquidated. In period 3, the loan is repaid to the depositor, unless the banker decides to abscond (which he can only do if the bank has not been liquidated).

B. The Contracting Structure

Contracts are arranged in period 0. The monopolist banker offers the profit-maximizing contract among those which yield the depositor at least S in expected returns. (If no such contract exists or the best such contract yields negative profits, then none is offered.)

¹⁵In the single-depositor case, the assumption that the signal takes only two values is not restrictive. In fact, the multidepositor model of the subsequent section can be reinterpreted as a single-depositor model with multivalued signals.

The universe of contracts in this structure is as follows. A contract is a function from a space of announcements Σ into *outcomes*. An outcome is a pair (P, Λ) , where $\Lambda \in \{0, 1\}$ is an indicator variable equaling 1 if liquidation is mandated and 0 otherwise. P is the mandated repayment. (Of course P will only be received if the banker does not abscond.)¹⁶

If the contract only specifies one outcome, we call it a "simple contract"; otherwise we call it a "compound contract." We have already described the two kinds of simple contracts: the simple liquidating contract and the simple nonliquidating contract. A straightforward application of the revelation principle demonstrates that, for the single depositor case, contracts need never contain more than two outcomes, because the signal the depositor may observe has only two values. We can identify the announcements in a compound contract with assertions by the depositor that he has observed one or the other signal. Thus, a compound contract consists of a quartet $(P_b, \Lambda_b, P_g, \Lambda_g)$.

Each contract generates a sequential game in which the depositor chooses the level of investment in information-gathering (e) and the announcement he makes as a function of the signal he receives. The banker chooses whether to abscond as a function of the announcement made by the depositor and the realization on the investment. An *optimal* contract is one for which there is a sequential equilibrium that generates maximum profits consistent with the depositor's receiving expected returns equal to the amount S .

¹⁶As it stands, the specification of the contract is incomplete in two technical respects. First, the specification of the outcome should include a specification of the banker's response (i.e., whether he chooses to abscond) as a function of the announcement $\hat{\sigma}$ and of the realization T_i . However, in almost all contracts, the banker's response is easily discerned: he absconds if $P_{\hat{\sigma}} > gAT_i$ and does not abscond if $P_{\hat{\sigma}} < AT_i$. Only in the case of indifference would it be necessary to specify his response in detail. Second, the contract does not include the possibility of randomized outcomes. These can be shown never to dominate deterministic outcomes.

THEOREM 1:¹⁷ *The optimal contract in the problem takes one of the following four forms:*

- a) *a simple nonliquidating contract*
- b) *a simple liquidating contract; in this case,*

$$AT_1 < P \leq M$$

- c) *a compound contract composed of two simple nonliquidating contracts ($\Lambda_b = \Lambda_g = 0$); in this case,*

$$P_b \leq AT_1 \text{ and } AT_1 < P_g \leq AT_2$$

- d) *a compound contract composed of one simple liquidating contract and one simple nonliquidating contract ($\Lambda_b = 1, \Lambda_g = 0$); in this case,*

$$AT_1 < P_b < P_g \leq AT_2.$$

If the optimal contract is a compound contract, then the depositor invests in the signal; if it is a simple contract, he does not. In the case of compound contracts, absconding occurs if and only if the signal was *g* but the low-value outcome T_1 was realized.

We call contract d "demandable debt." It works as follows: after making the deposit, the depositor invests in learning what the likely outcome will be. If he receives the bad signal, he opts for liquidating the bank. This delivers a payment with certainty. If he receives the good signal, he opts for not liquidating the bank. This promises a higher payment but runs the risk of the banker's absconding.

Contract c works in virtually the same way. The only difference is that the guaranteed payment in the case of a bad signal is sufficiently low that the banker will never wish to abscond and so it is not necessary to use liquidation to hold him in place. Since liquidation always involves social costs, it is not difficult to demonstrate that in any case where contract c is feasible, it dominates contract d. We will (with prejudice) describe contract c as a "nuisance contract."

Next, we provide a characterization of when the various contracts will be observed.

We do so under the assumption that the signal is "accurate" (i.e., ρ_g is high and ρ_b is low, so that the signal is a good predictor of the state) and the signal is "cheap" (so that I is small). It is easily demonstrated that, if the signal is sufficiently inaccurate or sufficiently expensive, a compound contract is not useful.

THEOREM 2: *If the signal is sufficiently cheap and accurate; then there exist values S^* and \hat{S} , such that the optimal contract depends on the required returns S in the following way: for $S \leq AT_1$ the simple, nonliquidating contract is optimal; for $S \in (AT_1, S^*]$, the nuisance contract is optimal; for $S \in (S^*, \hat{S}]$, demandable debt is optimal; and for $S > \hat{S}$, no contract is feasible.*

In other words, demandable debt will be observed when the returns that depositors can receive in alternate investments are relatively high.

III. Multiple Depositors with Independent Signals

In this section, we develop a model for the case in which a number of depositors enter into contracts with the banker. As before, each depositor has one dollar to invest, and the banker has one "project" he can pursue. The project costs Y and yields a total return of YT_i , which takes one of two values. Any deposits the banker receives in excess of Y can be used to yield the same competitive return S that depositors have available to them on their own. Deposits in excess of Y will be identified with "reserves."

We make the following natural assumptions about the difference between the two forms of bank assets, "project" and "reserves." If the bank is liquidated, the value of the project decreases by $1 - L$; the value of the reserves is unchanged.¹⁸ If the banker

¹⁷Proofs of theorems are outlined in the Appendix.

¹⁸This assumption is natural, given that we regard the project as requiring the banker's expertise and regard the reserves as invested in publicly available technologies.

TABLE 1—PAYOFFS ON EACH OF THE THREE NODES OF THE GAME TREE

Contract	Banker receives	Depositors receive
Liquidation	$(1-L)T_1Y + (Z-Y)S - P$	P
No liquidation		
Banker absconds	$(1-A)T_1Y$	$(Z-Y)S$
Banker does not abscond	$T_1Y + (Z-Y)S - P$	P

absconds, then he takes the projects with him and receives $(1-A)YT_1$. The depositors retain the entirety of the reserves.¹⁹ We strengthen assumption (2) as follows:

$$(4) \quad L < A(T_1/T_2).$$

There are Z individuals available to enter into a contract with the bank. Of these individuals, K can receive signals by investing at a cost I ; for the remainder, the cost of receiving a signal is prohibitive.²⁰ Signals are independent and identically distributed (i.i.d.) conditional on T_i . For any individual, a "bad" signal is associated with reduced likelihood of the high-productivity state T_2 , so $\rho_b < \rho_g$, as before.

Supposing that all K individuals have invested in the signal, let N be the number who receive the "bad" realization. Given the i.i.d. structure, N is a sufficient statistic for T_i , and the probability that the realization is T_2 decreases with N .

A. The Contract from the Banker's Viewpoint

We start by examining only the incentive problem for the banker, taking the behavior of all depositors as given. We will return to

the individual depositors' incentives in the succeeding subsection. For now, we assume that all K individuals who can invest in obtaining the information do so and report it truthfully.²¹ A *contract* specifies an aggregate payment P and a liquidation decision Λ as functions of the number of depositors who announce observations of the bad signal. (In the succeeding subsection, we will investigate a scheme for dividing aggregate payments among the depositors.) Note therefore that the contract is the direct generalization of the contract in the previous section to a case of multiple signals.

After the announcement of the signals, the game tree is as before: if a liquidation is not mandated, the banker makes a decision whether to abscond. Table 1 describes the payoffs on each of the three nodes of the game tree.

The *optimal contract* maximizes the banker's expected profits subject to three restrictions.

- 1) The expected payments to the depositors equal their aggregate reservation level:

$$SZ + KI.$$

That is, all depositors must be compensated for the opportunity cost of their funds; in addition, any monitors must be compensated for the cost of monitoring.

- 2) In the case of liquidation, actual payment cannot exceed what is assumed feasible; as before, we suppose that a liquidated investment Y pays off at most MY to the depositors. Thus, the total pay-

¹⁹An alternative assumption is that, if the banker absconds, he takes the entirety of the reserves as well. The assumption in the text is natural if we regard absconding as occurring by siphoning a project into a less desirable project whose returns accrue directly to the banker. The assumption in this footnote is natural if we regard absconding as occurring when the banker piles the loot into the stagecoach and heads out of town.

²⁰This is the simplest structure of supply of signals; it can be generalized. Alternatively, the cost of investing in a signal could be determined in a general equilibrium model.

²¹It will be clear that, as long as the cost of investing in the signal is sufficiently low, it is optimal to have all individuals with cost I make the investment.

ment to depositors out of the project and the reserves is

$$P \leq MY + (Z - Y)S \quad \text{if } \Lambda = 1.$$

- 3) Finally we must consider the banker's incentive to abscond. If liquidation does not occur, then the banker will prefer to abscond whenever

$$AT_1Y < P - (Z - Y)S.$$

If the inequality is reversed the banker prefers not to abscond.

As before, we define \hat{S} to be the least upper bound of feasible expected returns to depositors from the project; if the required rate of return exceeds \hat{S} , no contract is feasible. \hat{S} can be calculated explicitly.

Our first result is that, for required returns which are sufficiently high (but less than \hat{S}), the optimal contract calls for liquidation when the number of bad signals is high, and not when the number of bad signals is low. When the number of bad signals is low, there is a positive (but small) probability that the banker will abscond.

THEOREM 3: *For an interval of values of S , $(\underline{S}, \hat{S}]$, the optimal contract has the following form: there exists \underline{N} such that:*

If $N > \underline{N}$, $\Lambda(N) = 1$ and

$$P(N) = MY + (Z - Y)S;$$

If $N < \underline{N}$, $\Lambda(N) = 0$ and

$$P(N) = AT_2Y + (Z - Y)S.$$

In other words, the contract has informed agents announce whether their signal was bad. If more than a critical number \underline{N} announce bad signals, the bank is liquidated. If fewer than \underline{N} announce bad signals, the bank is not liquidated, and the banker chooses to abscond if the productivity draw was low.²²

²²If exactly \underline{N} announce bad signals, the optimal contract has a randomization between liquidation and nonliquidation. We omit the details.

Note that Z is arbitrary in this contract. As Z increases, the optimal P increases one-for-one: additional deposits beyond those invested in the project are held in reserves and returned to the depositors with certainty.²³

B. Depositor Incentives

It remains to be shown that the total aggregate payment to depositors specified in the previous section can be divided among depositors in such a way as to maintain the incentives for low-cost-information depositors to invest in the signal and to report it truthfully. In this section, we derive a demandable-debt contract that achieves this goal.

We make the following assumptions about the population of monitors and the signals:

ASSUMPTIONS: *There are large numbers of potential depositors (Z) and potential monitors (K). The cost of monitoring (I) is small. The probability of any one monitor receiving a bad signal is small. The probability of a bad realization of T is small (although the losses can be large).*

In modeling a bank, each of these assumptions seems natural to us. The assumptions allow us to model the distribution of the number of bad signals as a Poisson distribution. More precise criteria for "small enough" or "large enough" are indicated in the complete appendix (available upon request). Note that as long as I is sufficiently

It can be shown that, for values of S below this range, it will be useful to have two thresholds rather than one. For a range of values of bad signals received, it will be optimal to reduce the promised payment, rather than liquidate the bank. This is analogous to the nuisance contract discussed previously, and as before, it can be precluded by sufficiently high reservation levels of return.

²³Here, reserves are used solely for redistributing payouts between monitors and nonmonitors in an incentive-compatible way. In a richer model, banks would choose between holding reserves and investing more in higher-earning projects.

TABLE 2—PAYOFF TO DEPOSITOR WHO ANNOUNCES g

Project realization	Payoff to depositor announcing g	
	Number of depositors announcing $b < \underline{N}$	Number of depositors announcing $b > \underline{N}$
T_1	$\frac{AT_2 + (Z - Y)S - RN}{Z - N}$	$\frac{MY + (Z - Y)S - RN}{Z - N}$
T_2	$\frac{(Z - Y)S - RN}{Z - N}$	$\frac{MY + (Z - Y)S - RN}{Z - N}$

small, it is always optimal to have all the potential monitors engage in investment.

The contract for all depositors is identical. *Ex post* depositors will pick one of two announcements within the contract. Since there are three information possibilities (observing g , observing b , or not making an investment), there will have to be some pooling in the outcomes. We will build a contract in which it is incentive-compatible for the depositors who have made no investment to pool with those who have observed the good draw.

Each depositor's payoff depends on his announcement and the signal (if any) he observes. We let the symbol $EU(\hat{\sigma}, \sigma)$ denote the expected return for a depositor who observes signal σ and announces signal $\hat{\sigma}$.

Individual depositors are subject to two sorts of constraints: participation constraints (i.e., the contract must give expected returns that are sufficient for depositors to participate) and incentive constraints. From the point of view of the individual depositors, the contract must satisfy the following requirements.

- 1) Always announcing g gives an expected return of S , which exceeds the expected return from always announcing b . This means that depositors with high costs of gathering information will be willing to participate in the contract in the manner specified.
- 2) Announcing the observation truthfully gives a return of $S + I$, which exceeds the return from lying. If conditions in requirement 1 are satisfied as well, then individuals with a cost of I for investing

are willing to make the investment in monitoring and report truthfully.

These constraints for individual depositors can be written as follows:

$$\lambda EU(\hat{g}, g) + (1 - \lambda) EU(\hat{g}, b) \\ = S \geq \lambda EU(\hat{b}, g) + (1 - \lambda) EU(\hat{b}, b)$$

$$\lambda EU(\hat{g}, g) + (1 - \lambda) EU(\hat{b}, b) \\ = S + I \geq \lambda EU(\hat{b}, g) + (1 - \lambda) EU(\hat{g}, b)$$

where λ is the prior probability of signal g .

The scheme we consider has payments of a particularly simple form: any depositor announcing b receives the payment R with certainty. We can call an announcement b a "withdrawal of funds." If more than \underline{N} depositors announce b , the bank is liquidated; otherwise, it is not, and the banker has the option of absconding. In any event, those depositors who do not announce b evenly split the aggregate payment to depositors described in the previous section, less the funds withdrawn. We call this scheme a "standard demandable-debt contract."

Under a standard demandable-debt contract, of course,

$$EU(\hat{b}, b) = EU(\hat{b}, g) = R.$$

However, for depositors who do not withdraw their funds, the payment depends on the number of depositors N who do withdraw, and on whether the banker absconds. Table 2 describes the payments for a depositor who announces g .

For example, if more than \underline{N} depositors withdraw funds, then the bank is liquidated,

and according to the contract, the total payment to depositors P is $MY + (Z - Y)S$; that quantity, less the withdrawn deposits RN is split among the remaining depositors $Z - N$, yielding the quantity in the right-most column of the table. The remaining numbers are calculated in a similar fashion.

Given the probabilities of the realizations of T_i and the probability of each signal contingent on T_i , it is a straightforward matter to calculate $EU(\hat{g}, b)$ and $EU(\hat{g}, g)$. For this scheme, the incentive and participation constraints reduce to the following:²⁴

$$EU(\hat{g}, b) = R - I/(1 - \lambda) \\ S > R.$$

When an aggregate contract of the sort described in the previous section is optimal, it can always be implemented with a demandable-debt scheme, as stated in the following theorem.

THEOREM 4: *Under the distributional assumptions and the conditions of the previous theorem, the optimal outcome can be achieved with a simple demandable-debt contract.*

The role of reserves in our model warrants discussion. By holding reserves, the bank is able to guarantee early payment to a small number of monitors (those who receive bad signals) without forcing the bank to be placed into receivership. Reserves allow the bank to commit to the sequential-service constraint (early withdrawals by those who run the bank), which supports the implementation of the contract between bankers and depositors. More familiar justifications for bank reserve holding include the usefulness of reserves in meeting stochastic demands for conversion into gold

(say, due to foreign-transactions needs of depositors) or the contribution of reserves to an optimally diversified portfolio of bank assets. Our model adds to these transactions and portfolio motivations for holding reserves an "incentive-compatibility" demand for reserves.

C. Transactability and Demandable Debt

Thus far, we have argued that demandable-debt intermediation may arise in order to permit profitable investment opportunities to be realized. In our models, there is no demand for transactability; therefore, assets are valued entirely based on expected return. Historically, however, an important feature of demandable-debt instruments has been their use as a medium of exchange. In this subsection, we briefly consider the implications of our model for the liquidity of demandable debt.

It is important to note from the outset that transactable instruments need not be demandable. Postdated bills of exchange and postdated bank notes were physically transactable instruments that existed in the 19th century in the United States (Davis R. Dewey, 1910). Their primary difference from demandable debt was that they could be redeemed, not on demand, but only on the date of maturity. Since such instruments could be maturity-matched, they would seem to have none of the disadvantages of demandable debt. Nonetheless, demandable debt outcompeted these as a medium of exchange.

In order to explain the relative liquidity of demandable debt, one must explain why the ability to redeem a bank note or deposit on demand makes people more willing to accept it as a means of payment. We argue that, under demandable debt, monitors and nonmonitors alike are better informed of the market value of the debt instrument at all times.²⁵

²⁴The constraints initially have two equalities that must be satisfied. However, given the fact that the total expected payments equal $SZ + KI$, as they do by construction of the demandable-debt contract, one of the equations is redundant: if the informed depositors are each receiving $S + I$, then the uninformed depositors are automatically receiving the remainder, or S per depositor.

²⁵In a different context, Gorton and Pennacchi (1990) also employ this definition of liquidity. They show that debt instruments may be more liquid than equity because debt instruments reduce the potential

The fact that "the bank is open" (that monitors have not called for a liquidation) is revealing to nonmonitors. In the simplest, one-monitor case, the fact that the bank is open is fully revealing, because the signal that the monitor receives takes one of two values. In the multimonitor case, the fact that the bank is open is not fully revealing; it only indicates that fewer than the threshold number of bad signals have been announced. Even this information, however, places a lower bound on the value of the bank's liability.²⁶ If the liquidity of an asset depends on the extent to which information about its value is shared, then one would expect demandable debt to have been more liquid than other contracts with which it competed (see George Akerlof, 1970; Benjamin Klein, 1974). Thus, it may be possible to view the liquidity of bank claims as a by-product of the solution to the agency problem.

While we argue that the transactability of demandable debt enhanced its attractiveness, it is interesting to note that demandable-debt banking predates the transactability of demandable debt.²⁷ Thus, the desirability of demandable-debt contracting does not seem to have depended crucially on the transactability of the instruments.

gains insiders can receive from trading. Their model does not, however, explain the special liquidity of demandable debt.

²⁶Historically, specie prices of bank notes published in bank-note "reporters" confirm the view that nonmonitors faced little price uncertainty for notes of banks that were open. Discounts on antebellum bank notes convertible on demand into specie traded in the home city at par; in distant locations, the discounts for notes mainly reflected the risk due to the time it would take to reach the city of issue. Typically, one could know the value of a bank's notes in New York by knowing the state in which the bank was located. These discounts typically remained small (between $\frac{1}{8}$ percent and 2 percent) and were subject to little variation. Discounts of notes for failed banks were not quoted in bank-note reporters or were subject to extreme variations across banks in the same locale and over time (see Calomiris and Schweikart, 1988).

²⁷For example, Roman banks issued demandable claims which were not transactable (A. W. Ferrin, 1908).

The "liquidity premium" that demandable debt enjoys can be included in our framework by reducing the level of the required return S on demandable debt by the amount of the liquidity premium. In other words, demandable debt would face a lower threshold reservation level to satisfy than the nonliquidating compound contract. This implies an expansion of the parameter values for which demandable debt is preferred over the "nuisance" contract.

IV. Summary

We have argued that historical demandable-debt banking can be understood as the optimal means of incentive-compatible intermediation in an environment of asymmetric information with potential for fraudulent behavior on the part of the banker. Monitoring by some depositors and runs by monitors who receive bad signals ensure sufficiently high payoffs to depositors in states of the world that would otherwise lead to malfeasance by the banker.

Agency problems are inherent in banking. Depositors entrust their endowments to bankers, who decide how to invest them and have essentially unfettered immediate control over the depositors' funds. We capture this agency problem in a simple way by allowing the potential for "absconding" by the banker. The banker has the ability to remove funds from the bank. Absconding is socially wasteful; if the banker steals funds from the bank, he uses a "leaky bucket," so that the amount he actually receives is less than the amount stolen.

If the required return for depositors is sufficiently high, then the banker may find it attractive to abscond, rather than make the promised payment to depositors. Anticipating this, depositors will be unwilling to entrust their funds to the banker, and efficient intermediation will not take place. In other words, the possibility for a banker to abscond may make it difficult for him to attract depositors to his bank.

We introduce a liquidation technology that allows depositors, at a cost, to prevent the banker from absconding and makes it

possible for the banker to attract depositors. We show that, under some circumstances, the optimal arrangement has the depositor choose whether to liquidate the bank, contingent on a costly signal he receives. In good states, it will pay for the banker not to abscond and to pay the depositor as promised; in bad states, absent a liquidation announcement, the banker will abscond rather than pay as promised. Thus, when monitors receive bad signals, they call for liquidation.

If the signal is perfect and costless to the depositor, liquidation will occur only when there are bad loan-investment realizations. If the signal is imperfect and costly, but not prohibitively so, it still makes sense to use the contingent liquidation contract, even though on occasion monitoring depositors may make errors in judging when to "run the bank" and force the bank to liquidate unnecessarily. Banks can fail either because the banker absconds or because the depositor initiates a run on the bank. The purpose of a run is to prevent absconding from taking place.

In the case of multiple depositors, the bank uses reserves to offer guaranteed payments to early withdrawers and to insulate itself from a few bad idiosyncratic signals. At the same time, under circumstances that probably would lead to costly absconding, depositors as a group are likely to order liquidation preemptively. The number of monitors and the threshold at which a bank liquidation is called for will be chosen optimally to minimize total expected costs of liquidation, absconding, and monitoring.

Limitations and Suggested Extensions

Our analysis has several important limitations. First, our goal is to explain the *historical* importance of demandable debt in banking. In today's more regulated environment, where for example, regulations on clearing through the Federal Reserve System have favored demandable-debt instruments and where deposit insurance makes depositor monitoring less important, demandable debt may persist simply as an artifact of regulation.

Second, our framework does not consider the possibility of trade in bank shares. Unlike the historical context in which demandable debt arose, in today's more sophisticated financial markets, shares of financial intermediaries are actively traded. In this richer context, equity trading could conceivably provide a superior disciplinary alternative to demandable debt and contingent liquidation. For example, leveraged buy-outs offer a possible alternative means to prevent managerial misconduct and provide rewards that make monitoring incentive-compatible.

Third, our account is one of individual banks and individual bank liquidations, not of systems of banks or economy-wide bank panics. We are only attempting to model the operation of demandable debt in normal times, when the rules require banks to pay on demand. In historical practice, the provisions of demandable debt, including liquidation, were suspended during crises (see James G. Cannon, 1910; Calomiris and Schweikart, 1988). That is to say, demandable debt was a contingent rule; it required banks to meet the threat of runs in response to idiosyncratic problems, but it allowed banks to escape convertibility on demand in the face of systemic disturbances. Only individual bank difficulties led to placing a bank in receivership. Suspension and interbank relations during panics are important as well, but doing this topic justice requires a larger analysis than the one we have undertaken in this paper (see Calomiris and Kahn, 1989; Gorton, 1989; Calomiris and Gorton, 1990).

Fourth, our model relies on a crude and extremely stylized incentive problem characterized by the "leaky bucket" with which the banker can abscond. This leaky-bucket assumption is useful, because it allows us to model the problem in an extremely simple way, but it raises natural questions as to whether the degree of leakiness necessary to generate the results is at all realistic. After all, if the banker's own stake is less than 1 percent of the value of the assets, then it would be necessary that more than 99 percent of the value of the assets leak from the bucket in good times in order to keep the banker from absconding.

A more reasonable interpretation of our story is as a simplification of a multiperiod account, in which the banker is in fact choosing whether to engage in malfeasance today, when the decision not to engage in malfeasance always leaves the option open for tomorrow. Suppose that the returns to a bank's investments are intertemporally correlated. Then, in a good realization, the banker may be unwilling to engage in malfeasance because it will destroy the prospects for future returns (including the possibility of future malfeasance), even without assuming the bucket implausibly leaky.²⁸ Thus, it is important to investigate multiperiod versions of our model to determine whether a consistent account can be generated with plausible parameter values.

Finally, our model does not include any demand for liquidity. We have intentionally limited the model in order to emphasize the difference between our account and those accounts that depend on liquidity demand. Nonetheless, this limitation means that the model is not adequate to investigate the relation between demandable debt and transactions demand. Although we have briefly and informally considered the links, formal models combining the consumption-flexibility and monitoring accounts of banking are an important goal for future research.

APPENDIX: SKETCHES OF PROOFS

To conserve space, we briefly describe the proofs for each of the four theorems. The complete Appendix is available from the authors on request.

PROOF OF THEOREM 1:

The claim that an optimal contract must conform to one of the four cases listed in the theorem is equivalent to the following claims.

- a) If the promised payment is less than the minimum absconding tax (AT_1), then liq-

uidation is never called for, since absconding is socially wasteful and simple debt repayment is always credibly preferred *ex post* by the banker.

- b) If the optimal contract is a compound contract, then it cannot specify liquidation in all states, since in that case there would be no incentive to invest in signals. If liquidation is going to be called for, it must be that it is only called for under the bad signal.
- c) If the optimal contract involves monitoring and contingent debt claims (the depositor announces one of two values to be repaid), then the amount announced contingent on the bad signal will be lower than the one announced contingent on the good signal, and the lower amount will be less than the minimum absconding tax.

PROOF OF THEOREM 2:

When $S < AT_1$, it is immediate that a simple debt contract is optimal. When the banker chooses between the demandable-debt and nuisance contracts, the banker will always choose the nuisance contract when it is feasible, because it is less socially wasteful than demandable debt. In the nuisance contract, social waste occurs through absconding when a good signal is received but a bad outcome is realized. In the demandable-debt contract, an additional source of waste is the liquidation cost when the bad signal is received. It can be shown that, as the reservation level of the depositor rises, liquidation will eventually be required to increase the depositor's returns beyond what is feasible in the nuisance contract. The use of either form of compound contract requires that the costs of receiving the signal be sufficiently low and the signal's accuracy be sufficiently high to warrant investment in the signal.

PROOF OF THEOREM 3:

The optimal contract is designed to give the depositors their required expected return while minimizing expected social waste from absconding and liquidation. The optimal contract in general involves dividing the possible values of N into three regions. For

²⁸We are grateful to an anonymous referee for suggesting this interpretation.

high values of N , the contract mandates liquidation. For intermediate values of N (a nuisance region), liquidation is not mandated, but aggregate payment is set sufficiently low that absconding never occurs. For low values of N , liquidation is not mandated, and payment is set sufficiently high that absconding takes place in bad states. It can be shown that, as the reservation level of depositors rises, the middle nuisance region disappears, in order to expand the range of higher depositor returns achieved through liquidation or high but uncertain payments.

PROOF OF THEOREM 4:

Given the payoff structure, one can write monitors' and nonmonitors' individual expected returns as functions of the signals received and announced by each, given the probability of other depositors' signals and actions. Tedious but straightforward calculation demonstrates that, for Z and N sufficiently large, the returns so calculated satisfy individual incentive and aggregate feasibility constraints. Finally we show that N sufficiently large can always be found, provided the probability of the good outcome exceeds a certain minimum level.

A Model of Homogeneous Input Demand Under Price Uncertainty

By FRANK A. WOLAK AND CHARLES D. KOLSTAD*

This paper examines the empirical validity of a model of homogeneous input demand under price uncertainty in which firms trade off expected input cost against its variability (risk) in selecting the optimal input supplier mix. Using recent work in time-series econometrics, this model is applied to the Japanese steam-coal import market, where five suppliers compete: China, the Soviet Union, South Africa, the United States, and Australia. (JEL L10, L72)

The purpose of this paper is to derive and examine the empirical validity of a model of homogeneous input demand under price uncertainty. The motivation for this investigation is the common observation that firms simultaneously purchase a homogeneous factor of production from a variety of suppliers each charging a different price. Moreover, there are many instances when the price from one supplier is consistently above that of all other suppliers for an extended period of time yet firms continue to purchase from this supplier. This observation appears to violate the criterion of expected cost minimization for input choice.¹ An at-

tempt to explain these anomalies suggests that firms trade off the level of expected input cost against its variability in deciding how to allocate total input demand across available suppliers. By purchasing inputs from a variety of suppliers, the firm is diversifying away some of the price risk associated with satisfying demand from the single least-expected-cost supplier.²

Although the marginal rate of substitution (MRS) between risk and cost is not directly observable, we develop a methodology for empirically estimating this magnitude from a time-series of input purchases. This MRS is an estimate of the firm's risk preferences at the expected cost-risk pair selected. If we assume that this MRS between risk and cost is constant across all expected cost-risk pairs, then an input-price risk premium can be calculated. Subject to this assumption, the input-price risk premium is the percentage above the current

We thank seminar participants at Stanford University, the University of California-Berkeley, the University of Texas, the University of Washington, Purdue University, and the Norwegian School of Economics for comments on earlier drafts. Tom MaCurdy, Randy Mariger, Paul Newbold, Roger Noll, and Agnar Sandmo deserve special mention for their helpful comments. Vivian Hamilton expertly prepared the figures. We especially thank an anonymous referee for thoughtful comments and suggestions on the previous version of the paper. His many contributions are too numerous to mention individually. The final version of this paper was prepared while Wolak was a National Fellow of the Hoover Institution.

¹For the sake of simplicity, assume that the price series are independent and identically distributed draws from a multivariate distribution. The null hypothesis of equal means for the prices becomes less likely the

greater the number of observations that one price series remains above the others. Clearly, if firms are minimizing expected cost, they would purchase all of this input from the least-expected-price supplier. Hence, in this simple case, the nonzero market share of the consistently high-priced supplier is, with high probability, a violation of the expected-cost-minimization criterion of input choice.

²Previous authors (Agnar Sandmo, 1971; Raveendra N. Batra and Aman Ullah, 1974; Roger D. Blair, 1974) have theoretically examined the comparative statistics of firm behavior under input and output price uncertainty.

TABLE 1—SUMMARY STATISTICS FOR PRICES AND QUANTITY SHARES
(SAMPLE PERIOD: MAY 1983–MAY 1987)

Country	Mean price. ($\frac{10^3 \text{ yen}}{\text{metric ton}}$)	Standard deviation of price	Mean quantity share	Standard deviation of quantity share
China	10.49	2.60	0.087	0.025
Soviet Union	8.95	1.67	0.036	0.015
United States	14.00	3.07	0.119	0.052
South Africa	10.57	2.39	0.213	0.054
Australia	10.54	2.45	0.547	0.087

expected market price a firm would pay for riskless input supply. If the firm's preferences imply a declining MRS between risk and expected cost (the MRS depends on the level of these two magnitudes), then the risk premium we compute is only an upper bound on the percentage above the current expected price the firm would be willing to pay for riskless input supply. Our risk-diversification model of input demand also provides a framework for quantifying the relative risk characteristics of input prices similar to the framework for assessing the relative risk of securities in the capital-asset-pricing model (CAPM). This framework will be discussed later in the paper.

We have chosen the Japanese steam-coal import market for an empirical implementation of the risk-diversification model. This coal is primarily used in Japanese cement-manufacturing and electricity-generation facilities. Although this coal is supplied to a variety of consumers in Japan, the Ministry of International Trade and Industry (MITI) is the centralized decision-maker which coordinates all international steam-coal transactions and hence is analogous to the firm in our model of input demand. We estimate the risk-diversification model and examine its validity as an explanation for the observed patterns of Japanese steam-coal imports.

The specific puzzle we address is: why do the Japanese not buy the least-expected-cost coal? Three observations about the time-series properties of the vector of yen prices and quantities of steam coal imported from

the five suppliers—China, the Soviet Union, the United States, South Africa, and Australia—provide evidence against the expected-cost-minimization model of input choice. Table 1 gives the mean price in thousands of yen per metric ton and the mean quantity share, as well as the standard errors for both of these quantities, for these five countries over our sample period.

The first observation is that the price of United States coal is above that of all other suppliers throughout the entire sample period, yet the United States supplies an average of 11.9 percent of all steam coal imported to Japan during this period. The second observation is that the price of steam coal from the Soviet Union is consistently below the price of all other suppliers throughout the sample although it consistently has the smallest share of the Japanese steam-coal import market. These two observations are confirmed by the sample means of the prices given in Table 1. The final puzzle is that South Africa and Australia have approximately the same mean price over the sample, although for all observations over this same period the share of Japanese steam-coal imports from Australia is consistently more than double that from South Africa. We find that the risk-diversification model and the apparent risk characteristics that it implies for each supplier provide an economically plausible explanation of the operation of the Japanese steam-coal import market.

The remainder of the paper proceeds as follows. The next section introduces nota-

tion and then derives the risk-diversification model of input demand. Section II discusses the econometric framework underlying the estimation of this model. This section treats the specification of a stochastic process describing the behavior of the vector of input prices over time and also describes the form and sources of other uncertainty in the model. Section III provides a brief overview of the Japanese steam-coal import market, to match up the theoretical model of Section I with the actual workings of this market. Section IV describes the application of this framework to the Japanese steam-coal import market. It presents several formal and informal tests of our structural model embodying the risk-diversification hypothesis. In Section V, we present the general implications of modeling input demand under uncertainty within this risk-diversification framework. For example, we are able to calculate the risk premium described earlier and a measure of market-specific risk associated with each of the supply-price processes. We can also derive a relationship between these measures of market-specific risk and the optimal expected supply price for each supplier. We then examine the validity of these implications of our structural model within the context of the Japanese steam-coal market. The paper closes with a short discussion of the policy implications of the empirical results and suggestions for future applications of this framework.

I. A Risk-Diversification Model of Firm Input Demand

Consider a firm using a set of inputs to produce one or more outputs. All inputs to production but one are termed "nonrisky" in that their price is nonstochastic. Output prices are also nonstochastic. The price of one of the inputs (the "risky" input) is uncertain. Supplies of that input must be contracted for *ex ante* before the price uncertainty is resolved. If the firm is risk-averse, it may increase its utility by substituting away from the risky input or by utilizing a variety of suppliers in an effort to reduce risk through diversification.

We begin by defining notation:

- p_{it} : price of risky input from supplier i in period t ($i = 1, \dots, n$);
- q_{it} : quantity of risky input demanded from supplier i in period t ($i = 1, \dots, n$);
- \mathbf{p}_t : n -dimensional vector of risky-input prices in period t ;
- \mathbf{q}_t : n -dimensional vector of risky-input quantities demanded in period t ;
- \mathbf{r}_t : vector of prices of nonrisky inputs in period t ;
- \mathbf{s}_t : vector of quantities of nonrisky inputs in period t ;
- $\boldsymbol{\pi}_t$: vector of deterministic output prices in period t ;
- \mathbf{y}_t : vector of output quantities in period t ;
- I_t : information set available to firm at time t , containing \mathbf{p}_s ($s \leq t-1$);
- μ_t : $E(\mathbf{p}_t | I_t)$, conditional expectation of \mathbf{p}_t ;
- Σ_t : $E\{(\mathbf{p}_t - \mu_t)(\mathbf{p}_t - \mu_t)' | I_t\}$, conditional variance of \mathbf{p}_t ;
- $\mathbf{1}$: n -dimensional vector of 1's;
- Q_t : $\mathbf{1}'\mathbf{q}_t$, total demand for risky input in period t ;
- \mathbf{w}_t : \mathbf{q}_t / Q_t , n -dimensional vector of risky-input quantity shares.

The firm is governed by the implicit production relation $f(\mathbf{y}_t, \mathbf{s}_t, Q_t) = 0$. Rather than maximize profits, because it is risk-averse, in each period the firm maximizes the expected utility of profits given the vectors of nonstochastic input and output prices and the information set I_t . We make the simplifying assumption that the firm's expected utility can be written as a function of the conditional expectation of profits, $E(\Pi_t | I_t)$, and the conditional variance of profits, $V(\Pi_t | I_t)$, where

$$\Pi_t = \boldsymbol{\pi}_t' \mathbf{y}_t - \mathbf{p}_t' \mathbf{q}_t - \mathbf{r}_t' \mathbf{s}_t$$

is the firm's profit in period t . This assumption about firm preferences is similar to that made for investor preferences in the CAPM. As in the CAPM, this assumption is equivalent to either the firm having a utility function that is quadratic in profits or the random input prices \mathbf{p}_t having a multivariate Gaussian distribution. Thus, the firm's prob-

lem is, at every time period,

$$(1) \max_{\mathbf{q}_t, \mathbf{s}_t, \mathbf{y}_t} U[E(\pi'_t \mathbf{y}_t - \mathbf{p}'_t \mathbf{q}_t - \mathbf{r}'_t \mathbf{s}_t | I_t), \\ V(\pi'_t \mathbf{y}_t - \mathbf{p}'_t \mathbf{q}_t - \mathbf{r}'_t \mathbf{s}_t | I_t)] \\ \equiv U[\pi'_t \mathbf{y}_t - \mathbf{r}'_t \mathbf{s}_t - E(\mathbf{p}'_t \mathbf{q}_t | I_t), \\ V(\mathbf{p}'_t \mathbf{q}_t | I_t)]$$

subject to

$$f(\mathbf{y}_t, \mathbf{s}_t, Q_t) = 0, \quad \mathbf{v}'_t \mathbf{q}_t = Q_t, \quad \mathbf{q}_t, \mathbf{s}_t, \mathbf{y}_t \geq 0.$$

This optimization problem is equivalent to the two-stage process whereby first an optimal portfolio of suppliers is chosen to yield a given Q_t . Then, in the second stage, the proper balance is struck among outputs (\mathbf{y}_t), nonrisky inputs (\mathbf{s}_t), and the total amount of the risky input (Q_t). The portfolio of \mathbf{q}_t for a given Q_t , and F (described below) is the solution to

$$(2) \max_{\mathbf{q}_t} U[F - E(\mathbf{p}'_t \mathbf{q}_t | I_t), V(\mathbf{p}'_t \mathbf{q}_t | I_t)] \\ \text{subject to } \mathbf{v}'_t \mathbf{q}_t = Q_t, \quad \mathbf{q}_t \geq 0.$$

Substituting this vector of optimal supplier quantities back into the objective function yields the optimal-value function $U^*(F, Q_t | I_t)$, where F is net revenue from nonrisky inputs and outputs. Thus, U^* defines the highest level of utility obtainable for a given F and Q_t ; the optimal \mathbf{q}_t^* (which is a function of F and Q_t) has been substituted in for \mathbf{q}_t . The second-stage optimization problem uses this optimal-value function to determine the utility-maximizing total quantity of the risky input (Q_t), nonrisky inputs (\mathbf{s}_t), and outputs (\mathbf{y}_t) as follows:

$$(3) \max_{\mathbf{y}_t, \mathbf{s}_t, Q_t} U^*(\pi'_t \mathbf{y}_t - \mathbf{r}'_t \mathbf{s}_t, Q_t | I_t)$$

subject to

$$f(\mathbf{y}_t, \mathbf{s}_t, Q_t) = 0, \quad Q_t, \mathbf{s}_t, \mathbf{y}_t \geq 0.$$

Solving (3) with U^* defined by (2) is equivalent to solving (1).

Because we are only interested in the choice of the portfolio of suppliers of the risky input, we will focus on (2). Ignoring the possible negativity of any elements of \mathbf{q}_t , the Lagrangian for (2) is

$$(4) \quad L = U(F - \mu'_t \mathbf{q}_t, \mathbf{q}'_t \Sigma_t \mathbf{q}_t) \\ + \eta(Q_t - \mathbf{v}'_t \mathbf{q}_t)$$

where η is the Lagrange multiplier on the constraint that the sum of purchases from all of the suppliers equals Q_t . The first-order conditions from (4) are

$$(5) \quad \frac{\partial L}{\partial \mathbf{q}_t} = -U_1 \mu'_t + 2U_2 \mathbf{q}'_t \Sigma_t - \eta \mathbf{v}' = 0$$

where U_i is the derivative of U with respect to its i th argument. Equation (5) can be solved for the scalar η using the constraint $\mathbf{v}'_t \mathbf{q}_t = Q_t$:

$$(6) \quad \eta = \frac{2U_2 Q_t - U_1 \mathbf{v}' \Sigma_t^{-1} \mu_t}{\mathbf{v}' \Sigma_t^{-1} \mathbf{v}}$$

Substituting (6) back into (5) and rearranging gives the following expression for the optimal vector of risky input shares:

$$(7) \quad \mathbf{w}_t^0 = \left[\frac{\lambda_t Q_t + \mathbf{v}' \Sigma_t^{-1} \mu_t}{\mathbf{v}' \Sigma_t^{-1} \mathbf{v}} (\Sigma_t^{-1} \mathbf{v}) - \Sigma_t^{-1} \mu_t \right] \frac{1}{\lambda_t Q_t}$$

where $\lambda_t = -2U_2/U_1$. Dividing λ_t by 2 gives the producer's marginal rate of substitution between expected costs and risk. It is, of course, a function of I_t , Q_t , and F . However, Q_t and F , and thus λ_t , are the result of solving (3). Rather than solve (3) explicitly, we make an assumption about the functional form of λ_t . Several specifications for λ_t are possible. The first is simply $\lambda_t = \lambda$ for all t . Another, which is the specification we adopt, is that $\lambda_t = \lambda/Q_t$ (i.e., $\lambda_t Q_t$ is a constant). This specification for λ_t has the attractive feature that it makes the optimal input share (7) invariant to Q_t . Thus, for fixed μ_t and Σ_t , if there is a secular rise in

the level of productive activity in the firm, supplier shares remain constant. This expression for λ_t simplifies (7) to

(8)

$$\mathbf{w}_t^o = \left[\frac{\lambda + \mathbf{v}' \Sigma_t^{-1} \boldsymbol{\mu}_t}{(\mathbf{v}' \Sigma_t^{-1} \mathbf{v})} (\Sigma_t^{-1} \mathbf{v}) - \Sigma_t^{-1} \boldsymbol{\mu}_t \right] \frac{1}{\lambda}.$$

For notational ease in what follows we write (8) as

$$(9) \quad \mathbf{w}_t^o = \mathbf{S}_t(\boldsymbol{\mu}_t, \Sigma_t, \lambda).$$

Defining $\phi = 1/\lambda$, we can rewrite (8) as

(10)

$$\mathbf{w}_t^o = \left[\frac{1 + \phi(\mathbf{v}' \Sigma_t^{-1} \boldsymbol{\mu}_t)}{(\mathbf{v}' \Sigma_t^{-1} \mathbf{v})} (\Sigma_t^{-1} \mathbf{v}) - \phi(\Sigma_t^{-1} \boldsymbol{\mu}_t) \right].$$

Equation (10) gives the optimal-supplier-share vector as a function of ϕ , the relative weight attached to expected cost in the firm's optimal-input-choice problem, whereas (8) gives the same optimal supplier share as a function of λ , the relative weight attached to the conditional variance of input cost. Equation (10) will be used later when we examine the validity of our structural model of the risk-diversification hypothesis.

Given values for $\boldsymbol{\mu}_t$ and Σ_t , and knowing its value of λ , or equivalently ϕ , the firm can compute the optimal period- t input-supplier mix from equation (8). We assume that the firm knows or behaves as if it knows the parameters of the stochastic process determining the time path of the vector of input prices so that it can compute $\boldsymbol{\mu}_t$ and Σ_t for all t . Unfortunately, in order for us to implement this model and determine its empirical validity, we must estimate the parameters of this stochastic process. Therefore, we now turn to the econometrics of the risk-diversification model of input demand.

II. The Econometrics of the Risk-Diversification Model of Input Demand

In this section, we present our methodology for implementing the risk-diversification

model of input demand. There are two independent sources of uncertainty in this model. The first, what we call estimation error, arises from the estimation of $\boldsymbol{\mu}_t$ and Σ_t , the conditional mean and covariance matrix of the vector-valued price process. The second, what we refer to as optimization error, is included to account for any unobservable time-specific random shocks which may cause the first-order conditions (5) not to hold exactly each period.

This optimization error has the implication that we require the first-order conditions to hold only in expectation. Operationally, this means that (9) becomes

$$(11) \quad \mathbf{w}_t = \mathbf{S}_t(\boldsymbol{\mu}_t, \Sigma_t, \lambda) + \boldsymbol{\varepsilon}_t \equiv \mathbf{w}_t^o + \boldsymbol{\varepsilon}_t$$

where $\boldsymbol{\varepsilon}_t \in R^n$ is $\mathcal{N}(0, \Omega)$. Thus, the observed input-share vector (\mathbf{w}_t) equals the optimal input-share vector (\mathbf{w}_t^o) plus white noise. The restriction that $\mathbf{v}' \mathbf{w}_t = 1$ implies that $\mathbf{v}' \boldsymbol{\varepsilon}_t = 0$ and $\mathbf{v}' \Omega \mathbf{v} = 0$. We introduce this optimization error as a way to take into account the fact that there may be unobservable (to the econometrician) variables that affect the supplier shares actually selected which are not included in our model of input demand. Hence, despite requiring the total input supply to be deterministic, the model does allow random variation in quantities across suppliers from the utility-maximizing levels determined from our risk-diversification model.

Because our price series appear to be stationary in first-differences yet their levels roughly move together (there exists a stationary linear combination of the prices), our methodology for modeling the estimation error in $\boldsymbol{\mu}_t$ and Σ_t involves fitting an error-correction model for each price series:

$$(12) \quad \Delta p_{it} = c_i + \gamma_i z_{it-1} + \beta_i \Delta p_{it-1} + \xi_{it} \\ (i = 1, \dots, n; t = 1, \dots, T)$$

where $\Delta p_{it} = p_{it} - p_{it-1}$. To take into account the fact that, on average, the levels of these prices move together we include z_{it} , which is an estimate of the stationary linear combination of all of the prices. Following

Robert F. Engle and Clive W. J. Granger (1987) and James H. Stock (1987), we compute z_{it} as the residual from the regression of p_{it} on all other prices and a constant. Hence, z_{it} has a sample mean of zero. As shown in Stock (1987), because the parameters of the cointegrating regression converge to their true values at rate T , rather than the usual \sqrt{T} , the z_{it} may be effectively treated as the observed z_t in the estimation of the parameters of (12) and the computation of their \sqrt{T} -asymptotic distribution. We assume that $\xi_t = (\xi_{1t}, \xi_{2t}, \dots, \xi_{nt})'$ is distributed as a $\mathcal{N}(\mathbf{0}, \Sigma)$ random vector. This distributional assumption for ξ_t and the model (12) for p_{it} ($i = 1, \dots, n$) implies that the conditional variance of Σ_t equals a constant Σ for all t .

Besides embodying the cointegration property of \mathbf{p}_t , this model for each price series is consistent with the following logic. The constant term c_i takes into account the possibility that Δp_{it} may have a nonzero mean. By including this constant term, we are effectively allowing p_{it} to have a nonzero mean in its stochastic trend. The term in z_{it-1} , the error correction term, takes into account the fact that the amount z_{it-1} differs from its steady-state value will affect period t 's price change for this supplier. We would expect γ_i to be negative because, if z_{it-1} is positive (recall how z_{it} is estimated), this period's Δp_{it} should be lower than its mean to reflect a correction toward the steady state. The third term in Δp_{it-1} represents the impact of last period's price change on this period's price change.

The final model estimated for each price series should be such that the null hypothesis that $\xi_{it} \equiv E(p_{it} | I_t) - p_{it}$ is white noise cannot be rejected. Additional terms in Δp_{js} ($j = 1, \dots, n$; $s \leq t-1$) should be added to the model until this is the case. Clearly, a shortcoming of our approach is that there may be other variables besides lagged values of p_t that help to estimate μ_t . Nevertheless, in this paper we assume that I_t contains only lagged values of \mathbf{p}_t .

Let Γ_i denote all of the coefficients entering into (12) for Δp_{it} . Let $\mu_{it}(\Gamma_i, I_t)$ denote the conditional mean function for the i th price process. In this shorthand notation we

can rewrite (12) as

$$(13) \quad p_{it} = \mu_{it}(\Gamma_i, I_t) + \xi_{it} \quad (i = 1, \dots, n).$$

If we stack all of the Γ_i into a single vector Γ then we can write (13) in vector notation as:

$$(14) \quad \mathbf{p}_t = \mu_t(\Gamma, I_t) + \xi_t.$$

Once we fit a univariate model to each price series such that the null hypothesis that each ξ_{it} series is white noise cannot be rejected, we can construct a consistent estimate of Σ as follows:

$$\hat{\Sigma} = \frac{1}{T} \sum_{t=1}^T \tilde{\xi}_t \tilde{\xi}_t'$$

where $\tilde{\xi}_t = (\tilde{\xi}_{1t}, \tilde{\xi}_{2t}, \dots, \tilde{\xi}_{nt})'$ and $\tilde{\xi}_{it}$ is the ordinary least-squares (OLS) estimate of ξ_{it} . This completes the first step of our two-step procedure to obtain consistent estimates of Σ and Γ . In summary, the equation-by-equation OLS estimates of the Γ_i in (13) yield a consistent estimate of Γ , and because $\hat{\Sigma}$ is based on this estimate of Γ , it is also consistent. The next step of this procedure conditions on these estimates of Γ and Σ and computes [from (11)] estimates of λ and Ω by maximum likelihood (ML). This two-step process yields \sqrt{T} -consistent estimates of Γ , Σ , λ , and Ω which can be used as starting values in a full-model ML estimation procedure.

Combining the model determining \mathbf{w}_t in (11) with that determining \mathbf{p}_t in (13) yields the following nonlinear ML model:

$$(15) \quad \begin{bmatrix} \mathbf{p}_t \\ \mathbf{w}_t \end{bmatrix} = \begin{bmatrix} \mu_t(\Gamma, I_t) \\ S_t(\mu_t(\Gamma, I_t), \Sigma, \lambda) \end{bmatrix} + \begin{bmatrix} \xi_t \\ \epsilon_t \end{bmatrix}$$

where $E(\xi_t \epsilon_t') = 0$, because the estimation error is assumed to be independent of the optimization error.

The log-likelihood function is

$$\begin{aligned}
 (16) \quad \ln L = & -\frac{T(2n-1)}{2} \ln 2\pi - \frac{T}{2} \ln[\det(\Sigma)] \\
 & - \frac{1}{2} \sum_{t=1}^T \{[\mathbf{p}_t - \boldsymbol{\mu}_t(\boldsymbol{\Gamma}, \mathbf{I}_t)]' \\
 & \quad \times \boldsymbol{\Sigma}^{-1}[\mathbf{p}_t - \boldsymbol{\mu}_t(\boldsymbol{\Gamma}, \mathbf{I}_t)]\} \\
 & - \frac{T}{2} \ln[\det(\boldsymbol{\Omega})] \\
 & - \frac{1}{2} \sum_{t=1}^T \{[\mathbf{w}_t - \mathbf{S}_t(\boldsymbol{\mu}_t(\boldsymbol{\Gamma}, \mathbf{I}_t), \boldsymbol{\Sigma}, \boldsymbol{\lambda})]' \\
 & \quad \times \boldsymbol{\Omega}^{-1}[\mathbf{w}_t - \mathbf{S}_t(\boldsymbol{\mu}_t(\boldsymbol{\Gamma}, \mathbf{I}_t), \boldsymbol{\Sigma}, \boldsymbol{\lambda})]\}.
 \end{aligned}$$

Given the two-step \sqrt{T} -consistent estimates of $\boldsymbol{\Gamma}$, $\boldsymbol{\Sigma}$, $\boldsymbol{\Omega}$, and $\boldsymbol{\lambda}$ described above, by the logic of theorem 6.3.1 of Erich L. Lehmann (1983 p. 422), asymptotically efficient estimates of these parameters can be obtained by one iteration of a method-of-scoring type of algorithm. Alternatively, starting from these consistent estimates and running this iterative procedure to convergence also yields asymptotically efficient estimates of these parameters.³

³We use the procedure suggested by Ernst R. Berndt et al. (1974) to compute the iterative maximum-likelihood estimates of these parameters. To simplify the computational complexity of the problem, we estimate $\boldsymbol{\Sigma}$ and $\boldsymbol{\Omega}$ in terms of the parameters of the Cholesky decomposition of their inverses. Recall that $\boldsymbol{\Sigma}^{-1}$ can be written as \mathbf{LDL}' , where \mathbf{L} is a lower triangular matrix with 1's along the diagonal and \mathbf{D} is a diagonal matrix. The determinant of $\boldsymbol{\Sigma}^{-1}$ is the product of the diagonal elements of \mathbf{D} . This decomposition simplifies the terms in the log-likelihood function containing the determinant of $\boldsymbol{\Omega}$ and $\boldsymbol{\Sigma}$ to a product of four diagonal elements in the former case and the product of five diagonal elements in the latter case. By the invariance property of maximum-likelihood estimation, the maximum-likelihood estimates of $\boldsymbol{\Omega}$ and $\boldsymbol{\Sigma}$ are equal to the inverse of the maximum-likelihood estimates of the Cholesky decomposition of the parameters of their respective inverse matrices. Consistent estimates of the standard errors can be obtained from the sample average of the matrix of outer products of the gradients of the log-likelihood function evaluated at the maximum-likelihood estimate of the parameter vector as described in Berndt et al. (1974) or as -1 times the matrix of second partial derivatives of the log-likelihood function evaluated at the same value of the parameter vector.

Given this framework for specifying and estimating our model of input choice under price uncertainty, we are now ready to apply it to the Japanese steam-coal import market. Before proceeding to the application, we first describe the history and operation of this market.

III. The Japanese Steam-Coal Import Market

Almost immediately after the 1973–1974 Arab Oil Embargo and the subsequent substantial increase in the world price of oil, the Japanese embarked on a plan, coordinated between business and government, for a stable domestic energy supply (Yuan-li Wu, 1977). Foremost among the methods Japan used to achieve this goal was to diversify both the suppliers and sources of energy. Prior to this event, Japan had an oil-based energy economy and obtained most of its oil from the Middle East and the United States. Following this embargo, Japan expanded its sources of oil to China and the Soviet Union and began to consider coal as a major source of energy.

At this time, Japan was importing coal primarily from the United States for use as coking coal in the production of steel. By the beginning of 1977, the Soviet Union, China, South Africa, and Australia had become consistent participants in this market, but the United States was still the major source of Japanese coal imports. By this time, Japan was also importing steam coal to be burned in coal-fired electricity-generation facilities. In response to the oil price rises, Japan quickly converted most of its cement-manufacturing plants from oil-fired to steam-coal-fired (Ercan Tukenmez and Nancy Tuck, 1984). During the next five years, the United States' share of the steam-coal market steadily declined, and the shares of South Africa and Australia increased considerably. The average volume of monthly steam-coal imports (as classified by the Japan Tariff Association) rose from approximately 300,000 metric tons per month in early 1977 to 1.5 million metric tons per month in early 1984 and eventually to close to 2.7 million metric tons per month in mid-1987.

This steam coal is imported through negotiations with Japanese trading companies in conjunction with MITI for delivery to the steam-coal-using facilities. Prices for coal are negotiated in terms of the currency of the country of origin of the coal, although sometimes in dollars. Hence, some of the price risk borne by Japanese consumers is due to foreign-exchange-rate risk. An additional source of price uncertainty to Japan arises from what are called demurrage costs. These costs are incurred when a ship picking up or delivering coal is unable to load or unload its cargo immediately upon arrival at port. These queuing costs at port are usually directly added to the delivered price of coal. In periods when loading or unloading facilities are operating at capacity, these charges can amount to a significant portion (approximately 10 percent) of the delivered price of coal (United States Department of Energy, 1981 p. 7).

Coal is purchased using three mechanisms: joint venture between buyer and supplier, long-term contract, and short-term supply agreement (this category includes spot-market purchases). In contrast to metallurgical coal, which is a highly specialized input to the production of steel and as a consequence is, for the most part, delivered on long-term contracts, the relatively simple uses of steam coal and the increasing flexibility of boilers to burn different types of coal make short-term supply agreements (less than one year) and spot-market purchases viable. The Japanese make substantial spot-market purchases from South Africa, the United States, and Australia, while spot purchases play a lesser role in the imports from China and the Soviet Union. As stated in a recent United States Department of Energy report, "At present, South Africa steam-coal exports to Asia are largely spot sales" (Tukenmez and Tuck, 1984 p. xxi).

Most long-term contracts and joint ventures allow for some flexibility in the prices charged for coal delivered on a given contract depending on current market conditions at the time of delivery, so that some of the price risk is due to the conditions in the spot market at the delivery date. Also, in

the case of long-term contracts and joint ventures, the Japanese trading companies often renegotiate the prices charged under these agreements if current market conditions favor their doing so. For example, when there is a downturn in the world coal market many of these contracts are renegotiated. This potential for renegotiation of long-term supply agreements based on current market conditions is another source of price uncertainty.

There is an abundance of anecdotal evidence for the validity of the risk-diversification model of input choice for the Japanese steam-coal import market. Various editions of the *MITI Handbook* published by Japan Trade and Industry Publicity, state that the two major policy goals for MITI in the area of energy and natural resources are: 1) a stable supply of energy resources and 2) stable prices of energy resources. One of the stated goals of the Coal Mining Department of MITI is "to smooth the importation of coal" (*MITI Handbook* 1979/1980 p. 82). Japan's desire for a stable, secure energy supply is well documented in Wu (1977), a study of Japan's response to the Arab Oil Embargo of 1973/1974. In addition, a U.S. Department of Energy study of coal trade in the Asian market states, "...in seeking diversification and security Japan seems willing to pay a premium to access stable coal supplies from the more expensive exporters, such as the United States..." (Tukenmez and Tuck, 1984 p. 3). This casual evidence coupled with the three puzzles concerning the time-series properties of the prices and quantities of imports of steam coal to Japan stated in the Introduction makes for a challenging application of our risk-diversification model of input choice that is also of substantial policy interest.

IV. Application to the Japanese Steam-Coal Import Market

Time-series of prices and quantities of steam coal⁴ imported into Japan from

⁴Steam coal is classified by the Japan Tariff Association as high- and low-ash coal other than coking coal.

China, the Soviet Union, the United States, South Africa, and Australia are available on a monthly basis from *Japan Exports and Imports: Commodity by Country*, compiled by the Japan Tariff Association. All prices are in units of thousands of yen per metric ton. The quantity units are metric tons. The Appendix describes the construction of these magnitudes from the raw data. Note that the input-choice problem is invariant to the absolute price level. The normalization of prices will only affect the magnitude of λ . To make shares and prices of approximately the same magnitude in the estimation procedure, prices were normalized so that the sum of the sample means of all of the prices of coal is equal to 1.

The sample period from March 1983 to May 1987 was selected because the structure of the Japanese steam-coal import market seems stable over this period. Confirmation of this point is that, despite a growing total quantity of steam coal imported, the share of the market served by each supplier shows no statistically significant serial correlation or trend over this period. This empirical observation provides further support for our selection of a form for λ , that makes the optimal supplier shares independent of Q_t because, as mentioned in Section III, Q_t nearly doubled over our sample period.

The first step of the estimation procedure is to test for cointegration among the five price processes over the sample. As discussed in Engle and Granger (1987), the presence of cointegration is necessary for

the validity of the error-correction model of the price processes given in (12). To confirm that each of the univariate price processes is integrated of order one, we performed David A. Dickey and Wayne A. Fuller's (1979) unit-root tests on the levels and first differences of each series. The models run for each test are

$$(17) \quad \Delta p_{it} = \alpha + \beta_1 p_{it-1} + \beta_2 \Delta p_{it-1} + e_{it}$$

for the test for a unit root in the levels and

$$(18) \quad \Delta^2 p_{it} = \alpha + \beta_1 \Delta p_{it-1} + \beta_2 \Delta^2 p_{it-1} + d_{it}$$

for the test for a unit root in the first differences. In both cases, the null hypothesis is that $\beta_1 = 0$, or more precisely, the backshift operator polynomial of the AR portion of the ARIMA representation of x_t (x_t represents either the raw or first-differenced price series) has the following factorization: $\phi(B) = (1 - B)\phi^*(B)$, where all of the roots of $\phi^*(z) = 0$ are greater than 1 in modulus. The results of these tests are given in Table 2. For all of the tests in terms of the levels of the price series, there is little evidence against the null hypothesis of a unit root, indicating that nonstationarity of the price series in levels cannot be rejected. In contrast, the null hypothesis of a unit root in the first-differenced series is decisively rejected for all of the series at the 0.01 level of significance, providing strong evidence for the stationarity of the first-differenced series. The critical value for the test is from table 8.5.2 of Fuller (1976 p. 373). For the present case, an assumption implicit in the Dickey-Fuller test—that the true value of α is 0 in (17) and (18)—may not be valid given the substantial decline in prices over the sample period. For this reason, we also report Kenneth D. West's (1988) corrected t statistic on β_1 in (17) and (18). This statistic is asymptotically normal under the assumption that α in these two equations is nonzero. Computing West's t statistic amounts to correcting the usual OLS t statistic for the fact that the OLS estimate of the variance of the error term

Although, strictly speaking, steam coal differs across countries, it is primarily, if not exclusively, valued for its heat content. Consequently, only coal with the highest heat content is exported. Although the heat content of each shipment of coal to Japan during the sample period was not available, the heat content of coal for a representative sample of coal contracts from each of the supplier countries considered in this paper was available (TEX Report, 1986). For this representative sample, the mean heat content per ton of coal delivered was not significantly different across the supplier countries considered here. This provides support for our treatment of steam coal from various countries as a homogeneous product.

TABLE 2—DICKEY-FULLER (DF) AND WEST (W) TESTS FOR UNIT ROOTS

Country	p_{it} (DF)	Δp_{it} (DF)	p_{it} (W)	Δp_{it} (W)

Soviet Union	-0.5911	-6.0028	-0.6136	-6.1802
United States	-0.8124	-7.2048	-0.8452	-7.4585
South Africa	-0.0488	-5.4708	-0.0504	-5.5622
Australia	0.4913	-5.6874	0.5051	-5.7431

Notes: Critical value (0.01 level) for Dickey-Fuller test = -3.58; critical value (0.01 level) for West test = -2.33.

e_{it} in (17) or d_{it} in (18), is inconsistent if these errors are autocorrelated. West suggests a consistent estimate of this variance based on the sample autocorrelation function of the OLS residuals. To compute West's t statistic, we must first choose m , the number of sample autocorrelations to include in the estimate of the variance of the error in (17) or (18). We selected $m = 5$ because beyond this value of m the value of \hat{s} (in West's notation) did not appreciably change. These statistics are reported in the second column of Table 2. The one-sided critical value for these statistics is obtained from the standard normal distribution; the results of West's tests confirm the results of the Dickey-Fuller tests. This battery of tests is in line with the first requirement for the price processes to be cointegrated. The results suggest that each of the univariate price processes is integrated of order one.

The second requirement of cointegration is that some linear combination of the prices is stationary. To test this hypothesis, we utilize the augmented Dickey-Fuller (ADF) test recommended by Engle and Granger (1987). This test is based on the residuals from the cointegrating regression. The cointegrating regression for the i th supplier is the regression of p_{it} on a constant and the p_{jt} ($j \neq i$). The intuition behind this test is that, if the series are cointegrated, then the errors from this regression should be stationary. It is implemented via a Dickey-Fuller test [in the form of (17) given above] on the residuals from the cointegrating regression for p_{it} . The null hypothesis of a unit root in the residual process corresponds to noncointegration, and the alternative of stationarity of the residual process

TABLE 3—REGRESSION-BASED TESTS FOR COINTEGRATION

Country	Augmented Dickey-Fuller statistic
China	-6.0708

United States	-5.6352
South Africa	-5.7883
Australia	-3.4231

Notes: Critical values are -4.80 (0.01 level) and -4.15 (0.05 level).

corresponds to cointegration of the price processes. Table 3 contains these test statistics and their critical values. As can be seen from the table, the ADF tests on the residuals from the cointegrating regressions for China, the United States, and South Africa imply that the null hypothesis that the series are noncointegrating is rejected at the 0.01 level in favor of the alternative that they are cointegrating. For the Australia and Soviet Union cointegrating regression residuals, we find that the null hypothesis of noncointegration cannot be rejected at the 0.05 level. The critical values for the ADF statistics are those for the case $n = 5$ from Table 3 of Engle and Byung S. Yoo (1987). The results of this set of tests provide significant evidence in favor of the hypothesis that the five price series are cointegrating. These results support the use of (12) to model each price series.⁵

⁵We also performed the test for cointegration derived by Soren Johansen (1988). This test yielded a similar finding of cointegration.

Australia	-0.0032582 (0.0010532)	-0.12764 (0.12171)	-0.34435 (0.14205)	0.617483	1.9756

Note: Ordinary least-squares standard-error estimates are in parentheses below the coefficient estimates.

For each first-differenced price series, the model given in (12) with a constant term, z_{it-1} , and Δp_{it-1} was sufficient to represent adequately the behavior of each of the price processes over the sample and still not reject white-noise errors. Table 4 contains the results of these regressions. As expected, the signs of all of the parameters associated with the z_{it-1} are negative. Because of the presence of a lagged dependent variable in combination with z_{it-1} in the regression, the usual univariate Box-Pierce statistic for autocorrelation is not valid; instead, the auxiliary regression form of James M. Durbin's (1970) Lagrange multiplier (LM) test for AR(1) disturbances was computed. These statistics are asymptotically normal under the null hypothesis. For all of the models, there is very little evidence for this alternative against the null hypothesis of univariate white-noise errors. Generalizations of this LM test given in Trevor S. Breusch and Adrian R. Pagan (1980) against general fourth-order AR and MA processes were also performed, but the null hypothesis of white-noise errors could not be rejected for these cases either. As a test of the null hypothesis of a constant conditional variance of each of the price processes over time, we computed the LM test for ARCH errors derived by Engle (1982). This test statistic is computed as TR^2 from a regression of the squared residuals on lagged values of the squared residuals and a constant.

This statistic is asymptotically distributed as $\chi^2_{[k]}$ with k equal to the number of lagged residuals included in the auxiliary regression. These test statistics for the case of two lagged residuals are reported in Table 4. All of these statistics are considerably less than 5.991, the $\alpha = 0.05$ critical value from a $\chi^2_{[2]}$ random variable. Similar test results were obtained for the cases $k = 1$ and $k = 3$. The standard-error estimates for the coefficients reported in Table 4 are the usual single-equation ordinary least-squares (OLS) estimates, and as such do not take into account any of the restrictions of our structural model or the contemporaneous correlation between the ξ_{it} in the five price equations.

Conditional on these first-round estimates of the parameters of the price process, we then estimate λ and Ω by ML. Starting from the \sqrt{T} -consistent estimates of λ and Ω and the OLS estimates in Table 4, we then compute fully efficient ML estimates which impose the cross-equation restrictions implied by our risk-diversification model and the contemporaneous covariances between the ξ_{it} 's. Table 5 contains the converged ML estimate of Σ , the conditional covariance matrix of the price process. All ML parameter estimates were within two standard errors (using the consistent standard-error estimates computed from the converged ML parameter estimates as described in footnote 3) of the first-round set of consistent estimates of Γ ,

FIGURE 1. ACTUAL AND FITTED IMPORT QUANTITY SHARES FOR THE UNITED STATES FROM ML MODEL ESTIMATION

Σ , λ , and Ω . This result lends some credence to our ML estimation procedure, which jointly estimates Γ , Σ , λ , and Ω , and imposes the cross-equation restrictions implied by our structural model. These ML parameter estimates and associated consistent standard-error estimates allow an examination of the validity of the risk-diversification approach to input demand.

Figures 1 and 2 contain plots of the fitted versus actual values of the prices and shares from our ML model-estimation procedure

for the United States.⁶ The corresponding plots for the other four countries showed the same qualitative features as these plots and were therefore omitted to save space. The units on prices are thousands of yen per metric ton. The first thing to note from

⁶We are very grateful to a referee for suggesting many of the diagnostic tests and exploratory procedures discussed in the remainder of this section.

FIGURE 2. ACTUAL AND FITTED IMPORT PRICES IN THOUSANDS OF YEN PER METRIC TON OF STEAM COAL FOR THE UNITED STATES FROM ML MODEL ESTIMATION

these figures is that fitted prices follow actual prices much more closely than fitted shares follow actual shares. Nevertheless, the model fits well enough not to predict negative shares for any observations in our sample, despite the fact that the actual shares, especially those for the Soviet Union, are extremely close to zero. In order to give some idea of the explanatory power of our model we computed an " R^2 " for each of the price functions and share equations estimated. Analogous to the way that it is defined for the linear-regression model, we define $R^2 \equiv 1 - (\text{RSS}/\text{TSS})$, for

$$\text{RSS} = \sum_{t=1}^T (y_t - \hat{y}_t)^2$$

and

$$\text{TSS} = \sum_{t=1}^T (y_t - \bar{y})^2$$

where y_t is the dependent variable of the

TABLE 6— R^2 FOR PRICE AND SHARE EQUATIONS

Country	R^2	
	Price	Share
China	0.9527	0.3765

South Africa	0.9562	0.3632
Australia	0.9720	0.3642

equation, \hat{y}_t is the fitted value of y_t , and \bar{y} is the sample mean of y_t . In Table 6 we present these magnitudes for each price and share equation. Table 6 confirms the superior fit of the price equations. For the remainder of this section, we attempt to examine the validity of less restrictive models that include additional parameters or variables. We are unable to find substantial evidence against our structural model. Consequently, based on the specification tests discussed below, we conclude that this rather large unexplained variability in the

import shares is due either to factors that we have been unable to measure (which therefore cannot be incorporated into our model) or simply to nonsystematic deviations from optimizing behavior. We have modeled both of these phenomena by ϵ_t in (11).

We now discuss the tests of the restrictions implied by our structural model. All of them focus on the share equations, because our risk-diversification model implies restrictions on the parameters of these equations and on which variables enter these equations but no restrictions on the model estimated for the price process. These tests involve either testing the overidentifying restrictions of our model or testing for left-out variables. First we consider the tests for left-out variables. Because we are dealing with a time-series of import shares, one indication that we may have left out some important variable would be that the residuals from the share equations exhibit autocorrelation. To test for this we computed the Box-Pierce statistics for first-order autocorrelation for each of the residual vectors from the share equations. Under the null hypothesis of serially uncorrelated errors, these statistics are asymptotically distributed as $\chi^2_{[1]}$ random variables. As shown in Breusch and Pagan (1980), because there are no lagged dependent variables in the share equations, the Box-Pierce statistics are asymptotically equivalent to an LM test against AR or MA serial correlation of the order of the Box-Pierce statistic. These statistics are reported in Table 7. Tests for higher-order serial correlation yielded similar results.

Another potential left-out variable in the share equations is the lagged value of the share in each of the share equations. If there are rigidities in import shares due to the contractual nature of steam-coal purchases, one might expect some sort of model involving partial adjustment to the optimal share vector over time. As a consequence, lagged shares would help to explain the current values of the shares. To test this hypothesis we reestimated our complete model with lagged values of the dependent variable in each of the share equations. This

TABLE 7—TESTS FOR AUTOCORRELATION
IN SHARE EQUATIONS

Country	Test statistic

Note: Critical value = 3.841 for $\alpha = 0.05$.

entails adding four parameters to our model. Recall that summability of the shares requires us to drop one share equation in the estimation. The likelihood-ratio statistic against this alternative hypothesis, computed as twice the difference between the log-likelihood functions for the unrestricted and restricted models, is asymptotically distributed as a $\chi^2_{[4]}$ random variable. This test statistic is equal to 8.22, which is less than 9.488, the $\alpha = 0.05$ critical value for a $\chi^2_{[4]}$ test. Based on the results of this test, lagged shares do not add any statistically significant explanatory power to our structural model. These results are consistent with the view that, although a portion of each period's purchases are made on long-term contracts, a sufficient amount of coal is also bought on the spot market so that these long-term contracts do not impose binding constraints on MITI's ability to adjust its import shares to what it believes is optimal for that period.

Our structural model also implies various cross-equation restrictions between and within the price and share equations. These cross-equation restrictions require that the parameters of Σ , the conditional covariance matrix of \mathbf{p}_t , enter into the share equations in a very specific way. We now consider two tests of the validity of these cross-equation restrictions. First rewrite (10) as

$$(19) \quad \mathbf{w}_t = \frac{\Sigma^{-1} \mathbf{t}}{\mathbf{t}' \Sigma^{-1} \mathbf{t}} + \phi \left[\frac{\Sigma^{-1} \mathbf{t}' \Sigma^{-1}}{\mathbf{t}' \Sigma^{-1} \mathbf{t}} - \Sigma^{-1} \right] \boldsymbol{\mu}_t + \boldsymbol{\epsilon}_t.$$

The unrestricted form of this set of equations is

$$(20) \quad \mathbf{w}_t = \mathbf{A} + \mathbf{B}\boldsymbol{\mu}_t + \boldsymbol{\varepsilon}_t$$

where \mathbf{A} is an $n \times 1$ vector and \mathbf{B} is an $n \times n$ matrix. If we impose only summability ($\mathbf{1}'\mathbf{w}_t = 1$) on the vector of share equations, then this implies $\mathbf{1}'\mathbf{A} = 1$ and $\mathbf{1}'\mathbf{B} = 0$. After imposing these restrictions, we are left with 24 free parameters in \mathbf{A} and \mathbf{B} to estimate. Consequently, estimating (20) jointly with the price equations involves estimating 23 more parameters than does estimating (19) and the price equations, because ϕ is the only parameter estimated in (19) that is not also estimated in the price equations. Call this unrestricted model, which assumes only summability in the share equations, model S. Another set of restrictions is implied by the fact that $\boldsymbol{\Sigma}$ is a symmetric, positive definite matrix. By inspection of (19), one restriction on the structural model is that \mathbf{B} is symmetric. Combining the assumption that \mathbf{B} is symmetric with the summability assumption gives the restriction that the input-share equations are homogenous of degree zero in expected prices. If we impose symmetry and summability, this leaves 14 free parameters in \mathbf{A} and \mathbf{B} to estimate in equation (20). By the same logic as given above, moving from (20) with symmetry and summability to (19) requires imposing 13 nonlinear cross-equation constraints on the parameters of \mathbf{A} and \mathbf{B} . Call this more restricted model, which assumes summability and symmetry, model S&S. We also consider an additional restricted form of (20), which is not explicitly nested within (19) but embodies an interesting testable restriction about the impact of $\boldsymbol{\mu}_t$ on \mathbf{w}_t . This model assumes $\mathbf{B} = \mathbf{0}$, so that under this hypothesis, the conditional mean $\boldsymbol{\mu}_t$ is assumed to have no explanatory power in predicting import shares. Call this model BZ. For the model BZ, the import shares are assumed to be independent identically distributed draws rather than independent draws from a distribution with a conditional mean depending on $\boldsymbol{\mu}_t$.

The likelihood-ratio statistic testing for our complete structural model (15) against

the less restricted model S&S is equal to 20.02. This statistic, which is asymptotically distributed as a χ^2 random variable with 13 degrees of freedom, is less than 22.36, the $\alpha = 0.05$ critical value for the test. The likelihood-ratio test for (15) against the unrestricted model S is equal to 27.6. This statistic is asymptotically distributed as $\chi^2_{[23]}$. This statistic is less than the $\alpha = 0.05$ critical value of 35.17. The results of these hypothesis tests provide little, if any, evidence against the validity of the cross-equation restrictions implied by our structural model. Table 8 presents the ML estimates of \mathbf{A} and \mathbf{B} under the following three hypotheses: (i) the structural model given in (19) with the price-vector model in (14), (ii) model S with the price model (14), and (iii) model S&S with the price model (14). Although very few of the individual elements of \mathbf{A} and \mathbf{B} are precisely estimated, none of these parameter estimates is wildly inconsistent across the three models. As a general rule, the more restricted parameter estimate is always contained within two standard errors of the less restricted parameter estimate to its right. In other words, the approximate 95-percent confidence interval of the less restricted parameter estimate contains the corresponding more restricted parameter estimate. For example, in the case of B_{21} , the estimate from model S&S is 0.4219, which lies within approximately one standard error (0.7458) of the estimate of B_{21} from model S, 1.0158. In addition, the estimate of this parameter from model (19), 0.0731, lies within two standard errors (2.0×0.1775) of its estimate from model S&S.

To investigate the explanatory power of $\boldsymbol{\mu}_t$ for \mathbf{w}_t , we test the null hypothesis that $\mathbf{B} = \mathbf{0}$ against both S and S&S. The test statistic for BZ versus S&S is 31.81. Setting $\mathbf{B} = \mathbf{0}$ under S&S imposes 10 restrictions, so that the $\alpha = 0.01$ critical value for this hypothesis is 23.21. Consequently, BZ can be rejected against S&S at the 0.01 level of significance. The test statistic for BZ versus S is 39.39. Imposing $\mathbf{B} = \mathbf{0}$ relative to only summability of \mathbf{B} imposes 20 restrictions. The $\alpha = 0.01$ critical value for this test is 37.56, so the null hypothesis of BZ can be rejected against the alternative of model S.

Note: Estimated standard errors are shown in parentheses below the parameter estimates.

^aThe following definitions match the numbers with countries: China = 1, United States = 2, South Africa = 3, Australia = 4, and Soviet Union = 5. Some of the elements of A and B corresponding to the Soviet Union are not reported, because these estimates can be obtained from the summability restrictions.

^bThese are the estimates of A and B implied by the ML estimates of ϕ and Σ which arise from maximizing (16).

^cThe parameters in this column are remaining elements of B. They are listed in the following order from top to bottom: B_{15} , B_{12} , B_{13} , B_{14} , B_{25} , B_{23} , B_{24} , B_{35} , B_{34} , B_{45} . This order was selected to match the above-diagonal elements of B with their corresponding below-diagonal elements.

These two tests lead to the following weak conclusion: although the explanatory power of μ_i for w_i based on the R^2 criterion given in Table 6 is quite limited, it is statistically significantly different from no effect of μ_i on w_i .

One further test of our structural model attempts to address the question of whether or not λ , which determines the marginal rate of substitution between risk and return, is constant across the share equations. In

other words, is there a single rate at which expected cost is traded off against cost variability, independent of its source? To examine the hypothesis of a single marginal rate of substitution of risk for cost, we estimated our model subject to the summability restriction but allowing λ to vary across the share equations. Moving from this model to the model with a single λ involves imposing three restrictions, so that the likelihood-ratio test against this alternative hypothesis

TABLE 9—MAXIMUM-LIKELIHOOD ESTIMATE OF λ

Statistic	Value
$\hat{\lambda} \times 10^{-3}$	1.123
Standard error of $\hat{\lambda} \times 10^{-3}$	0.152
<i>t</i> statistic	7.365

would be asymptotically $\chi^2_{[3]}$ under the null hypothesis. This test statistic is 10.9, which lies above the $\alpha = 0.05$ critical value of 7.82 but below the $\alpha = 0.01$ critical value of 11.34. Consequently, we conclude that there seems to be some evidence against the hypothesis of a single MRS between risk and cost, but it is not overwhelming.

Having provided evidence in favor of our structural model as a reasonable summary of the observed data, we now turn to the question of the validity of the specific behavioral model giving rise to our structural model: the risk-diversification model of input choice. Table 9 contains the ML estimate of λ and its standard error.⁷ By substituting equation (8) into the log-likelihood function (16), we can see that the log-likelihood function is not defined at the point $\lambda = 0$. As a consequence of this, we cannot compute the distribution of $\hat{\lambda}$ under the hypothesis that $\lambda = 0$. However, for $\lambda = \varepsilon > 0$, the standard conditions necessary to test $H: \lambda = \varepsilon$ versus $K: \lambda > \varepsilon$ are satisfied. The data in Table 9 allow rejection (at a 0.05 level of significance) of the null hypothesis $\lambda = \varepsilon$ in favor of the alternative $\lambda > \varepsilon$ for all $872.96 > \varepsilon > 0$, where 872.96 is the solution in ε of $1.64 = (\hat{\lambda} - \varepsilon)/\text{SE}(\hat{\lambda})$, so that in this limited sense we can say that λ is significantly different from zero. Reparameterizing our model in terms of ϕ as given in (10), we obtain a likelihood function that is defined for all $\phi \in R$. Viewing our problem in this manner allows us to address the opposite question of whether or not Japan places a nonzero weight on expected cost in deter-

mining its optimal import mix. Applying the δ method to compute the asymptotic standard error of $\hat{\phi}$, we find that the null hypothesis that $\phi = 0$ can be rejected in favor of the alternative that ϕ is positive. These two views of our risk-diversification model allow us to conclude that, within the context of our structural model of input choice, Japan appears to attach a positive weight to both the conditional mean and conditional variance of total input cost in choosing its optimal supplier mix.

An informal but potentially informative check of our risk-diversification hypothesis is to compare the predictions of our model with those of the expected-cost-minimization model in terms of the deviations from the actual shares. Because the full maximum-likelihood function in (16) will tend to produce estimates of Γ and Σ that favor the risk-diversification model over the expected-cost-minimization model, we use the first-round estimates of the parameters of the price process (which do not impose any of the restrictions of our structural model) to perform this analysis. For comparison, we then present the results for final maximum-likelihood estimates.

The mechanics of our procedure are as follows. Our metric for comparison is the expected cost of the import mix purchased under each model. For the expected-cost-minimization model, for each time period t , this expected cost is computed by selecting the supplier with the smallest μ_{it} arising from our model for the price process and multiplying this expected price by the total quantity of coal delivered. This is precisely the expected cost for an agent using the expected-cost-minimization rule. Call this magnitude C'_{mc} . We then compute the difference between this expected cost and the expected cost of the actual bundle of imports purchased. Call this magnitude C'_{act} . Mathematically these expected costs are

$$C'_{mc} = \left(\min_i \mu_{it} \right) Q_t$$

$$C'_{act} = \mu'_t q_t$$

For the risk-diversification model, we compute the minimum-cost quantity mix that

⁷Other maximum-likelihood parameter estimates are not reported because of their agreement with (modulo two standard errors) the first-round estimates in Table 4.

yields the same conditional variance of cost as the actual quantities purchased. Define $V_t = \mathbf{q}_t' \Sigma \mathbf{q}_t$ as the conditional variance of the actual quantity vector \mathbf{q}_t . For each time period t , this minimum-conditional-cost quantity mix is the solution to

$$(21) \quad \min_{\mathbf{q}} \mathbf{q}' \boldsymbol{\mu}_t$$

subject to $V_t = \mathbf{q}' \Sigma \mathbf{q}$ and $Q_t = \mathbf{q}' \mathbf{v}$.

If \mathbf{q}_t^v is the solution to (21), then C_{rd}^t , the minimum cost of a quantity mix with variance V_t , is equal to $\mathbf{q}_t^{v'} \boldsymbol{\mu}_t$. We compute $C_{act}^t - C_{mc}^t$ and $C_{act}^t - C_{rd}^t$ for all observations. Because the absolute magnitudes of these differences in costs provide little intuition, we instead focus on the ratio of these differences to the actual expected cost. The sample average of $(C_{act}^t - C_{mc}^t) / C_{act}^t$ is approximately 0.169. This means that, averaging over our sample, the expected total import cost associated with the minimum-expected-cost criterion is 16.9 percent below actual expected import costs. The sample average of $(C_{act}^t - C_{rd}^t) / C_{act}^t$ is 0.035, so that, averaging over our sample, the minimum-cost import bundle having the same variance as the actual bundle imported, has an expected cost that is 3.5 percent below actual import costs. If we compute these two magnitudes using the final (as opposed to first-round) estimates of Γ and Σ , then the two numbers become 16.7 percent and 1.0 percent, respectively. Although there is an improvement in the conformity of the data to the risk-diversification model as a result of imposing the cross-equation restrictions between the share and price equations in the full maximum-likelihood procedure, the divergence of actual expected costs from those predicted by the risk-diversification hypothesis are minor when compared to the divergence of actual expected costs from those predicted by the expected-cost-minimization hypothesis. Although, as discussed above, the risk-diversification hypothesis cannot be explicitly tested due to the fact that the likelihood function is not well-defined at the point $\lambda = 0$, the evidence presented here suggests that it is a

superior model to the expected-cost-minimization model for describing the Japanese steam-coal import market.

V. Implications of the Risk-Diversification Model of Input Demand

We now examine the empirical implications of this estimated model of short-run input demand under price uncertainty. We are concerned with three general questions. What is the size of the risk premium associated with steam coal imported to Japan? What relationships between the observed prices and shares does the risk-diversification model imply, and are these relationships consistent with the observed data? How well does this model of input choice explain the three time-series properties of supplier prices and shares of steam coal imported to Japan discussed in the Introduction?

We first consider the question of the size of the risk premium on imported coal. To derive this magnitude, consider the mean-price versus standard-error-of-price frontier, plotted in Figure 3. Such frontiers can be plotted for each $(\boldsymbol{\mu}_t, \Sigma)$ pair in our sample. Figure 3 is constructed using $\hat{\Sigma}$, the maximum-likelihood estimate of Σ and $\bar{\boldsymbol{\mu}}$, the sample mean of $\boldsymbol{\mu}_t(\hat{\Gamma}, I_t)$, as a representative value of $\boldsymbol{\mu}_t$, where $\hat{\Gamma}$ is the ML estimate of Γ . Define $P_{pt}(\mathbf{w}) = \mathbf{w}' \mathbf{p}_t = \sum_{i=1}^5 w_i p_{it}$ as the actual weighted average price of steam-coal imports at time t , where $\sum_{i=1}^5 w_i = 1$. Let $E(P_{pt}(\mathbf{w})) \equiv \mathbf{w}' \boldsymbol{\mu}_t$ equal the expectation conditional on I_t of $P_{pt}(\mathbf{w})$ and $\sigma^2(P_{pt}(\mathbf{w})) \equiv \mathbf{w}' \Sigma \mathbf{w}_t$ equal its variance conditional on I_t .⁸ The mean-standard-error frontier given in Figure 3 comprises the set of $(E(P_{pt}), \sigma(P_{pt}))$ pairs such that $\sigma(P_{pt}(\mathbf{w}))$ is minimized over \mathbf{w} subject to the constraints $\mathbf{v}' \mathbf{w} = 1$ and $E(P_{pt}(\mathbf{w})) = K$, where K is some positive constant. Once a value of λ is specified, the solution of (2) implies a point on the mean-standard-error frontier corresponding to the optimal input mix

⁸For the remainder of this section, all expectations and variances are conditional on I_t , the firm's information set at time t .

FIGURE 3. EFFICIENT FRONTIER COMPUTED USING THE ML ESTIMATE OF Σ AND THE SAMPLE AVERAGE OF ML ESTIMATES OF μ_t

for a given (μ_t, Σ) pair. The point labeled $M(\hat{\lambda})$ in Figure 3, is the optimal import mix (w_t^o) for $\hat{\lambda}$, the ML estimate of λ for $\mu_t = \bar{\mu}$ and $\Sigma = \hat{\Sigma}$. Because the efficient frontier depends on μ_t and Σ , the location of the point $M(\hat{\lambda})$ also depends on the values of these two magnitudes.

As an alternative measure of the relative fit of our model versus the expected-cost-minimization model, for $\hat{\Sigma}$ and $\bar{\mu}$, we also plot the expected-cost-minimizing bundle (subject to nonnegative input shares) and the sample average of the import bundles actually purchased. The expected-cost-minimizing point corresponds to purchasing only from the Soviet Union and is labeled point C in Figure 3. The point corresponding to the sample average of the import shares purchased is labeled A. A comparison of the distance between $M(\hat{\lambda})$ and A to the distance between A and C, provides further evidence against the expected-cost-minimization model versus the risk-diversification model.

The slope of the mean-standard-error frontier at the point $M(\hat{\lambda})$ is the rate at which Japan substitutes decreases in ex-

pected price for increases in the standard error of price. Define $P_t^o = w_t^{o'} p_t$ as the price corresponding to the point $M(\hat{\lambda})$. Where the tangent line to the point $M(\hat{\lambda})$ intersects the expected-price axis represents the expected price Japan would be willing to pay for riskless coal at time t , assuming that the marginal rate of substitution between risk and cost at $M(\hat{\lambda})$ [the point corresponding to $(E(P_t^o), \sigma(P_t^o))$ in Fig. 3] is constant for all levels of expected cost and standard errors of cost. We denote this price P_t^z because the portfolio of suppliers giving rise to this price is analogous to the zero-beta portfolio in the capital-asset pricing model (CAPM) with no riskless asset. We define the risk premium at time t (RP_t) as

$$(22) \quad RP_t = \frac{E(P_t^z) - E(P_t^o)}{E(P_t^o)}.$$

This risk premium has an alternative interpretation which can be understood without reference to the CAPM. The value of RP_t given in (22) is exactly equal to

FIGURE 4. RISK PREMIUM (RP_t) FOR SAMPLE PERIOD

$-\varepsilon_{\mu_t^o, \sigma(P_t^o)}$, the negative of Japan's elasticity of import price risk with respect to expected import price. This elasticity is defined as

$$(23) \quad \varepsilon_{\mu_t^o, \sigma(P_t^o)} = \frac{d \log(\mu_t^o)}{d \log(\sigma(P_t^o))}$$

where

$$\mu_t^o = \mathbf{w}_t^{o'} \boldsymbol{\mu}_t \quad \text{and} \quad \sigma(P_t^o) = (\mathbf{w}_t^{o'} \boldsymbol{\Sigma} \mathbf{w}_t^o)^{1/2}$$

and where \mathbf{w}_t^o is defined in (7). In terms of the parameters of our structural model,

$$\varepsilon_{\mu_t^o, \sigma(P_t^o)} = - \frac{\sigma^2(P_t^o) \lambda}{\mu_t^o}.$$

Although $\varepsilon_{\mu_t^o, \sigma(P_t^o)} = -RP_t$, we still need to compute $E(P_t^z)$ in order to present other extensions of the analogy between the risk-diversification model and the CAPM.

An alternative methodology for computing P_t^z uses the intuition of the zero-beta CAPM. The price P_t^z arises from the portfolio of suppliers (weighted average price),

which has no market risk (market risk is defined as covariance with $P_t^o \equiv \mathbf{w}_t^{o'} \mathbf{p}_t$). To compute this portfolio, we solve for the minimum-variance weighted-average price subject to the constraint that its covariance with P_t^o is zero. The Lagrangian for this optimization problem takes the form

$$(24) \quad L = \frac{1}{2} \mathbf{w}_t^z' \boldsymbol{\Sigma} \mathbf{w}_t^z + \eta \left(\frac{1}{2} \mathbf{w}_t^z' \boldsymbol{\Sigma} \mathbf{w}_t^o \right) + \nu (1 - \mathbf{1}' \mathbf{w}_t^z)$$

where \mathbf{w}_t^z is the independent variable and η and ν are Lagrange multipliers associated with the constraints that the covariance of P_t^z with P_t^o is zero and that $\mathbf{1}' \mathbf{w}_t^z$ is equal to 1. The solution to (24) is

$$(25) \quad \mathbf{w}_t^z = \frac{\mathbf{w}_t^o - \mathbf{w}_t^{o'} \boldsymbol{\Sigma} \mathbf{w}_t^o (\boldsymbol{\Sigma}^{-1} \mathbf{1})}{1 - (\mathbf{w}_t^{o'} \boldsymbol{\Sigma} \mathbf{w}_t^o) (\mathbf{1}' \boldsymbol{\Sigma}^{-1} \mathbf{1})}.$$

Using (25) and our ML parameter estimates, we can compute $E(P_t^o) = \mu_t^o$ and $E(P_t^z)$ for all of our observations.

Figure 4 contains a time-series plot of RP_t based on the ML estimates of Γ , $\boldsymbol{\Sigma}$, and λ .

This risk premium ranges from 29 percent to 50 percent over the sample period, implying that Japan seems willing to pay 29–50 percent above the current market price for a supply of coal having no price risk. Recall that this calculation assumes that the marginal rate of substitution between risk and cost is constant over all risks and costs. If Japan's preferences for risk entail a declining marginal rate of substitution of risk for cost, then these numbers only represent an upper bound on the risk premium at time t . For some utility functions, they could be extremely conservative bounds on the risk premium. To illustrate this point, Figure 3 contains an indifference curve tangent to $M(\hat{\lambda})$ which exhibits a declining MRS.

By inspection of Figure 4, this risk premium exhibits an increasing time trend. A risk premium that increases with time is consistent with the view that, as Japan becomes more and more dependent on foreign sources of steam coal, as has been the case in recent years, the amount above the current weighted average market price Japan is willing to pay for coal with no price risk should increase. The interpretation of our results that is based on the elasticity of substitution between risk and cost [equation (23)] allows the following statement: at the point $M(\hat{\lambda})$, the loss in utility to Japan from a 1-percent increase in $\sigma(P_t^o)$ can be exactly offset by a 0.29–0.50-percent decrease in μ_t^o , depending on the time period in the sample.

We now turn to the issue of how well our risk-diversification model of input demand explains the time path of Japan's steam-coal import shares. To treat this issue, we first present one further implication of our model of input choice and discuss the applicability of this implication to our data. From equation (11), we know that the expected value of the observed vector of quantity shares is equal to the optimal vector of quantity shares based on μ_t , Σ , and λ . More precisely, the expectation of w_t is the vector of optimal import shares for μ_t , Σ , and λ , so that

$$E(w_t) = S(\mu_t, \Sigma, \lambda) = w_t^o.$$

This condition states that the expectation

of the actual import share Japan chooses is a point on the efficient $[E(P_{p_t}), \sigma(P_{p_t})]$ frontier. Using w_t^o , the optimal import-share vector for period t , we can construct a measure of risk for each supplier's price relative to $P_t^o = w_t^{o'} p_t$, analogous to the market-specific measure of risk for each security in the CAPM. For this reason, we denote the market-specific measure of risk for supplier i in period t by β_{it} and define it as

$$\beta_{it} = \frac{\text{Cov}(P_t^o, p_{it})}{\text{Var}(P_t^o)}$$

where p_{it} is supplier i 's price. The covariance and variance in the expression for β_{it} are conditional on I_t , the information set at time t . Consequently, because the composition of P_t^o will change each time period as μ_t changes, both the numerator and denominator of β_{it} will vary over time. Hence, β_{it} will also change over time. Figure 5 contains the plot of the β_{it} for all suppliers over the sample period. Recall, that, by construction, P_t^o has a β_t of 1 for all t , just as the β of the market portfolio in the CAPM is equal to 1.

Using logic similar to that used to derive the security market line in the CAPM, we can derive a relationship between the β_{it} and $E(p_{it}|I_t)$ as follows:

$$(26) \quad E(p_{it}|I_t) = E(P_t^z|I_t) + [E(P_t^o|I_t) - E(P_t^z|I_t)]\beta_{it}$$

where $E(P_t^o|I_t)$ is the conditional expectation of P_t^o and $E(P_t^z|I_t)$ is the conditional expectation of P_t^z . The derivation of this result exactly parallels the derivation of the zero-beta form of the security market line in the CAPM. The portfolio w_t^o is analogous to the market portfolio in the CAPM model. Thomas E. Copeland and J. Fred Weston (1983 pp. 198–200) provide a straightforward derivation of the zero-beta form of the security market line.

Note that relationship (26) depends on $E(P_t^o|I_t)$, a magnitude that explicitly depends on $S(\mu_t, \Sigma, \lambda) = w_t^o$, the optimal import shares derived from our risk-diversifi-

FIGURE 5. β 's OVER SAMPLE PERIOD, COMPUTED FROM EFFICIENT SHARES (β_{it})

cation model.⁹ Hence, another check of the reasonableness of our structural model is to recompute the β_{it} using w_t instead of w_t^0 to see whether or not there is a linear relationship between these β_{it} (call them β_{it}^a) and $E(p_{it}|I_t)$, as suggested by equation (26). Figure 6 contains a plot of the β_{it}^a . The levels and pattern of the β_{it}^a over time are quite similar to those followed by the β_{it} based on w_t^0 , but the time series of β_{it}^a is clearly more volatile than that of β_{it} . In Figure 7, we plot the sample average of the β_{it}^a against the sample mean of the μ_{it} . Although there are only five points on the plot, the relationship between the sample means of the μ_{it} and β_{it}^a is very well approximated by a straight line. Consequently, using the observed share data to construct the risk measures, a linear relation similar

to that in (26) seems to hold with $E(P_t^0|I_t)$ replaced by $E(P_t|I_t)$, where $P_t = w_t' p_t$.

We are now in a position to address the three puzzles presented in the Introduction. The first puzzle is why the United States remains in the market despite its consistently high price. Figure 5 shows that the United States consistently has the lowest market-specific measure of risk associated with it. In fact, β for the United States is negative in some periods, and for the most part it hovers around zero, indicating that United States coal is a good hedge against variations in the market price of coal. The very low market-specific risk associated with the price of U.S. coal explains why the United States services a sizeable share of the market even though its price path lies above those of the other four countries and has the second-largest conditional variance (see Table 5). Furthermore, the negative elements in the United States' row and column in Σ explains how this β close to zero comes about.

⁹We are grateful to a referee for suggesting the following procedure to examine validity of equation (26).

FIGURE 6. β 's OVER SAMPLE PERIOD, COMPUTED FROM ACTUAL SHARES (β_{it}^0)

FIGURE 7. PLOT OF SAMPLE MEAN OF β_{it}^a VERSUS SAMPLE MEAN OF μ_{it}

The second puzzle is why the Soviet Union is consistently the cheapest supplier but never captures much of the market. Figure 5 also shows that the Soviet Union consistently has the highest market-specific measure of risk. In addition, the Soviet Union price has the highest conditional variance (see Table 5). These two risk measures illustrate why the Soviet Union has the smallest market share despite having the lowest price in almost all periods. From equation (26), we can see that the high level of market-specific risk associated with this supplier must be compensated for in terms of a low expected supply price in order for Japan to have nonzero demand for this coal.

The last puzzle concerns why South Africa and Australia have similar prices but very different market shares. This can be answered by inspection of our estimate of Σ in Table 5. Australia has the smallest conditional variance in price, and more importantly, its price has virtually no conditional covariance with any of the other prices. Both of these points imply that its market share should be substantially larger than that of South Africa, which has a higher conditional variance and higher conditional covariances with the other suppliers besides Australia. Finally, the similar time-series behavior of the β 's associated with Australia and South Africa explain, in part, why the two price processes from these countries are very similar and why the sample averages of the two price series are essentially the same.

VI. Conclusions and Policy Implications

The risk-diversification model of input demand seems to provide a useful framework for making economic sense of several puzzling anomalies in the Japanese steam-coal import market. Clearly, there are other models and factors that could explain the observed market shares; however, as mentioned earlier, the substantial anecdotal evidence for the applicability of the risk-diversification model of input demand makes an examination of its validity of particular interest and relevance.

The policy implications of these results for suppliers of Japanese steam-coal im-

ports fall into two broad categories. The first, perhaps more naive, view of these results is that because Japan seems to be willing to pay a premium for stable prices, a country interested in supplying more of its coal to Japan should attempt to stabilize its price of coal in yen to Japan. This view ignores the fact that much of the price uncertainty is due to factors beyond the control of coal suppliers. Supply interruptions, domestic price inflation in the country of origin, demurrage costs, exchange-rate fluctuations, and price inflation in Japan all affect the price of coal in yen to Japan. Consequently, perhaps a more sophisticated view of these results is that, as long as each supplier's price process has some component of its variation that is linearly independent of the variation in the prices of other suppliers, this supplier should have a nonzero market share whenever its prices are not too high above the prices of the other suppliers.

Perhaps the most significant result to come out of our paper is the development of a rigorous but implementable methodology for representing input demand under price uncertainty and for investigating the hypothesis of risk-diversification behavior in that framework. Future applications of this risk-diversification model of input demand are plentiful. Any industry in which a large portion of variable costs is taken up by a single homogeneous factor of production represents a potential test of the risk-diversification approach to input demand.

APPENDIX

This appendix describes the construction of the price and quantity series used in the empirical analysis. On a monthly basis, The Japan Tariff Association (JTA) publishes *Japan Exports and Imports, Commodity by Country*. This document gives the quantity (in metric tons) and the value (in thousands of yen) of imports, by country of origin, of various types of coal. During the sample period from May 1983 to May 1987, Japan imported coking, anthracite, lignite, and steam coal, which the JTA further decomposed into eight commodity classes. In terms of the Japanese Ministry of Finance's *Com-*

modity Classification for Foreign Trade Statistics classification system, steam coal is defined as commodity numbers 27.01-129 and 27.01-199. Consequently, to construct the total quantity and value of steam-coal imports from each country for each month, we computed the quantity and value totals for each country over these two commodity numbers. The price in thousands of yen per metric ton for a given country is obtained by dividing total value of shipments in the month by the total quantity of shipments in that month. If contacted at the address given in the initial footnote, the first author is willing to provide a machine-readable file containing these price and quantity data on a floppy diskette in DOS format.

Sticky Prices As Coordination Failure

By LAURENCE BALL AND DAVID ROMER*

This paper links the "coordination failure" and "menu cost" approaches to the microeconomic foundations of Keynesian macroeconomics. If a firm's desired price is increasing in others' prices, then the gain from price adjustment after a nominal shock is greater if others adjust. This "strategic complementarity" leads to multiple equilibria in the degree of rigidity. Welfare may be much higher in the equilibria with less rigidity. Thus, nominal rigidity arises from a failure to coordinate price changes. (JEL E12, E30)

Keynesian macroeconomics waned in the 1970's because economists grew disenchanted with its weak microeconomic foundations. The central difficulty was that Keynesian models were based on ad hoc rigidities in nominal wages and prices. The 1980's produced two approaches to reviving Keynesian theory. The "menu cost" literature (N. Gregory Mankiw, 1985; George Akerlof and Janet Yellen, 1985) seeks to provide rigorous explanations for nominal rigidities. These papers argue that small frictions in price setting are enough to produce large nominal rigidities. In contrast, the "coordination failure" literature (Russell Cooper and Andrew John, 1988) abandons nominal rigidities and seeks alternative foundations for Keynesian models. The central idea is that many economic activities, such as production (e.g., John Bryant, 1983), trade (e.g., Peter Diamond, 1982), and investment (e.g., Nobuhiro Kiyotaki, 1988), exhibit "synergism" or "strategic complementarity": one agent's optimal level of activity depends positively on others' activity. Strategic complementarity can lead to multiple equilibria, with high-activity equilibria superior to low-activity equilibria.

Thus, an economy may be stuck in an "underemployment equilibrium" even though a superior equilibrium exists.

Models with nominal rigidities and models with coordination failures are often presented as competing paradigms.¹ This paper shows that this view is incorrect. We take a step toward unifying the foundations of Keynesian economics by showing that the two sets of ideas are highly complementary. Nominal rigidity arises from a failure to coordinate price changes. This failure has the essential features of coordination failures in previous models. Flexibility in one firm's price increases the incentives for other firms to make their prices flexible. This strategic complementarity leads to multiple equilibria in the degree of nominal rigidity. Equilibria with less rigidity (more active price adjustment) are often Pareto superior to equilibria with more rigidity.

These results contribute to our understanding both of coordination failure and of nominal rigidity. The range of Keynesian phenomena explained by coordination failures is greatly expanded. Previous coordination-failure models contain only real variables and thus ascribe no role to monetary policy or other determinants of nominal spending. Our results suggest that coordination failure is at the root of inefficient non-neutralities of money. Theories of nominal rigidities gain new empirical and policy im-

plications. As we argue below, strategic complementarity in price adjustment helps to explain variation in nominal rigidity across countries and over time. Our finding of coordination failure suggests a role for government intervention, either to improve coordination of price adjustment or to offset the effects of rigidity through active monetary policy.

We study the coordination of price adjustment in a model similar to those in Olivier Blanchard and Kiyotaki (1987) and Ball and Romer (1989a). Section I describes the model, and Section II presents our main results. In the model, imperfectly competitive firms decide whether to pay a small cost of adjusting prices after a nominal shock. Previous work shows that considerable rigidity can be an equilibrium even if it results in large, highly inefficient fluctuations in output. This paper shows that there are additional equilibria with less rigidity, and often with higher welfare. Specifically, for a range of realizations of the shock, both full adjustment of prices and complete non-adjustment are equilibria; this implies that an economy facing a distribution of shocks possesses a continuum of equilibrium degrees of rigidity. The size of the continuum is increasing in the degree of strategic complementarity in price adjustment.²

²The surveys of menu-cost models by Blanchard (1987) and Julio Rotemberg (1987) contain other discussions of multiple equilibria in the degree of rigidity. Rotemberg's argument is closer to ours. Costas Azariadis and Cooper (1985) and Roger Farmer and Michael Woodford (1984) present overlapping-generations models in which both flexible and sticky prices are equilibria. These models differ from ours both in the meaning of price rigidity and in the source of multiple equilibria. In overlapping-generations models, money serves only as a store of value. Thus, a sticky price level means sticky real asset prices. In our model, money is the medium of exchange, and so sticky nominal prices mean sticky transactions prices. In Azariadis and Cooper (1985) and in Farmer and Woodford (1984), the source of multiple equilibria is the more general fact that overlapping-generations models have a large indeterminacy of equilibria (Woodford, 1984); the flexible and sticky price equilibria are just two of many. In our model, multiple equilibria arise from the combination of menu costs and strategic complementarity in price-setting, and (with the minor exception discussed

Section III sketches two extensions of our analysis. First, we introduce heterogeneity among price setters, so that some prices adjust to a shock and others do not. There can be multiple equilibria in the proportion that adjust and, hence, in the size of the shock's real effects. Second, we consider a simple dynamic model in which firms choose between adjusting prices every period and every two periods. Here, there are multiple equilibria in the frequency of adjustment and, hence, in the dynamics of the price level. In addition, this example illustrates a difference between our model and other coordination-failure models: while the economy possesses multiple short-run equilibria, it converges to a unique long-run equilibrium.

Section IV concludes by discussing the model's empirical and policy implications.

I. The Model

The model is similar to the one in Ball and Romer (1989a), which is based on Blanchard and Kiyotaki (1987). While Blanchard and Kiyotaki specify both goods and labor markets, we assume for simplicity that the economy consists of "yeoman farmers" who sell goods produced with their own labor. That is, we suppress the labor market and focus on rigidities in output prices. Subsection A describes tastes and technology, and Subsection B describes how we measure nominal rigidity.

A. Tastes and Technology

There is a continuum of yeoman farmers indexed by i and distributed uniformly on $[0, 1]$. Each farmer produces a differentiated good, sells this product, and purchases the products of all other farmers. Farmers take each other's prices as given.

Farmer i 's utility function is

$$(1) \quad U_i = C_i - \frac{\varepsilon - 1}{\gamma \varepsilon} L_i^\gamma - z D_i$$

in footnote 7) complete rigidity and full adjustment are the only equilibrium responses to a shock.

where

$$(2) \quad C_i = \left[\int_{j=0}^1 C_{ij}^{(\varepsilon-1)/\varepsilon} dj \right]^{\varepsilon/(\varepsilon-1)}$$

and where L_i is farmer i 's labor supply; C_i is an index of farmer i 's consumption; C_{ij} is farmer i 's consumption of the product of farmer j ; z is a small positive constant (the menu cost); D_i is a dummy variable equal to 1 if farmer i changes his nominal price; ε is the elasticity of substitution between any two goods ($\varepsilon > 1$); and γ measures the extent of increasing marginal disutility of labor ($\gamma > 1$). The coefficient on L_i^γ in (1) is chosen for convenience. Finally, farmer i has a linear production function:

$$(3) \quad Y_i = L_i$$

where Y_i is farmer i 's output.

The utility function determines the demand for farmer i 's product, given aggregate consumption and the farmer's relative price:

$$(4) \quad Y_i^D = C \left(\frac{P_i}{P} \right)^{-\varepsilon}$$

where P_i is the price of good i , C is aggregate consumption, P is the aggregate price index, and

$$(5) \quad C = \int_{j=0}^1 C_j dj$$

$$(6) \quad P = \left[\int_{j=0}^1 P_j^{1-\varepsilon} dj \right]^{1/(1-\varepsilon)}$$

Farmer i 's consumption equals his real revenues:

$$(7) \quad C_i = \frac{P_i Y_i}{P}$$

[See Blanchard and Kiyotaki (1987) for derivations of (4)–(7).] Substituting (3), (4), and (7) into (1) yields farmer i 's utility as a function of aggregate consumption and his

relative price:

$$(8) \quad U_i = C \left(\frac{P_i}{P} \right)^{1-\varepsilon} - \frac{\varepsilon-1}{\gamma\varepsilon} C^\gamma \left(\frac{P_i}{P} \right)^{-\gamma\varepsilon} - zD_i.$$

To make nominal disturbances possible, we assume that money is required for transactions, so aggregate nominal spending equals the money stock:

$$(9) \quad PC = M.$$

Julio Rotemberg (1987) describes a specific transactions technology that gives rise to (9). Purchases must be made with money. At the start of the model's single period, a central bank distributes an amount of money M to farmers. A dollar can be spent only once during a period (velocity equals one), and farmers must repay the bank at the end of the period. These assumptions imply (9) and assure that the budget constraint (7) is satisfied.³

Substituting (9) into (8) yields

$$(10) \quad U_i = \left(\frac{M}{P} \right) \left(\frac{P_i}{P} \right)^{1-\varepsilon} - \frac{\varepsilon-1}{\gamma\varepsilon} \left(\frac{M}{P} \right)^\gamma \left(\frac{P_i}{P} \right)^{-\gamma\varepsilon} - zD_i.$$

³Two details of this story deserve mention. First, individuals choose how much money to receive from the bank. The bank equates the total demand for money to the supply, M , by adjusting the amount that agents are required to repay. The demand is infinite if the required repayment is less than one-for-one and zero if it is greater; thus, the equilibrium repayment is one-for-one. Second, aggregate nominal spending is $\int_{j=0}^1 P_j Y_j dj$. Using (7) and (5), this can be rewritten as $\int_{j=0}^1 P C_j dj = PC$. Thus, (9) follows from the assumption that aggregate spending equals M .

Obviously the ideas behind (9) are more general than Rotemberg's model. Blanchard and Kiyotaki derive (9) by putting money in the utility function. In a dynamic model, money can be introduced through a more realistic cash-in-advance constraint or through overlapping generations [although these models may not yield (9) exactly]. Our approach introduces money as simply as possible.

Differentiation of (10) shows that farmer i 's utility-maximizing price, neglecting the menu cost, is

$$(11) \quad P_i^* = P^\phi M^{1-\phi}$$

with

$$\phi = 1 - \frac{\gamma - 1}{\gamma\epsilon - \epsilon + 1} \quad 0 < \phi < 1$$

where ϕ is the elasticity of P_i^* with respect to the aggregate price level. Equation (11) implies that, in the absence of menu costs, symmetric equilibrium occurs when $P_i = P = M$. Finally, combining (10) and (11) yields farmer i 's utility as a function of real balances, the ratio of his price to the utility-maximizing level, and the menu cost:

$$(12) \quad U_i = \left(\frac{M}{P}\right)^{\gamma(1-\epsilon+\epsilon\phi)} \\ \times \left[\left(\frac{P_i}{P_i^*}\right)^{(1-\epsilon)} - \frac{\epsilon-1}{\gamma\epsilon} \left(\frac{P_i}{P_i^*}\right)^{-\gamma\epsilon} \right] - zD_i \\ = V\left(\frac{M}{P}, \frac{P_i}{P_i^*}\right) - zD_i.$$

The analysis below uses several properties of the function $V(M/P, P_i/P_i^*)$ in the vicinity of $M/P = 1$, $P_i/P_i^* = 1$, the equilibrium in the absence of menu costs. This function is increasing and concave in M/P : $V_1(M/P, P_i/P_i^*) > 0$, $V_{11}(M/P, P_i/P_i^*) < 0$ (subscripts denote partial derivatives). Intuitively, a rise in M/P benefits a farmer by raising aggregate consumption and thus shifting out the demand curve that he faces. Concavity means that farmers dislike fluctuations in demand. The source of this risk aversion is the increasing marginal disutility of producing output: $\gamma > 1$ in (1). Finally, since $P_i/P_i^* = 1$ maximizes utility by defi-

nition,⁴

$$V_2\left(\frac{M}{P}, 1\right) = 0 \\ V_{22}\left(\frac{M}{P}, 1\right) < 0 \quad \forall \quad \frac{M}{P}.$$

B. Nominal Rigidity

Here, we describe the basic experiment that we consider. The economy begins with $M = 1$ and $P_i = P_i^* = 1 \forall i$. One can think of this as the situation in an earlier period when the economy is at its long-run equilibrium. In the current period, a shock occurs: M changes to $1 + x$. Each farmer chooses between keeping his price at 1 or paying the menu cost and changing his price to the new P_i^* . We determine the circumstances under which adjustment and nonadjustment of prices are equilibria.

While natural, the assumption that prices initially equal 1 is ad hoc (the "earlier period" is not explicit). Therefore, in an Appendix we follow our earlier article (Ball and Romer, 1989a) in assuming that farmers choose initial prices optimally, given a distribution of shocks with mean 0. Farmers choose initial prices different from 1 (i.e., certainty equivalence fails), because utility is not quadratic. We find that the results in the text are altered only slightly.⁵

Our formulation assumes that farmers set prices in nominal terms and thus that they can eliminate the real effects of money only by adjusting their prices after observing M . A natural question is why farmers do not simply set indexed prices (i.e., announce a function relating their prices to M) and

⁴As this discussion suggests, our use of specific functional forms is not important for our main results. Aside from the properties of $V(\cdot)$ described here, the only essential assumption is strategic complementarity in utility-maximizing prices: P_i^* must be increasing in P .

⁵The less rigorous approach in the text is in a sense more realistic, since actual price rigidity is usually a failure to adjust from a previous price. This idea is captured rigorously in the dynamic model of Section III.

thereby eliminate the need for *ex post* adjustment.⁶ The answer is that indexing a price, like adjusting *ex post*, requires small amounts of effort. In this case, the "menu costs" include the costs of computing the number of dollars corresponding to indexed prices and of learning to think in real rather than nominal terms. As Bennett McCallum (1986) explains, it is easier to set prices in nominal terms—in units of money—because money is the medium of exchange. In other words, it is convenient to use the medium of exchange as the unit of account.

By assuming that if farmers achieve flexibility they do so through *ex post* adjustment, we are implicitly assuming that *ex post* adjustment is less expensive than indexation. Assuming the reverse does not change the basic character of our results. In this case, farmers choose between indexed prices and noncontingent prices before observing the monetary shock. They base their decision on the variance of the shock, which determines the expected cost of forgoing indexation. Just as our basic model produces multiple equilibria for a range of realizations of the shock, the alternative model produces multiple equilibria (indexation and nonindexation) for a range of variances.

II. Coordination Failure

This section presents our central results. Subsection A shows that both full adjustment of prices and complete nonadjustment are Nash equilibria for a range of sizes of the monetary shock. It follows that the economy possesses a continuum of equilibrium degrees of nominal rigidity. Subsection B compares welfare in the different equilibria.

A. Multiple Equilibria

We first determine when nonadjustment of all prices is an equilibrium. This is how

⁶In this model, indexation of individual prices to the aggregate price level would not accomplish the same thing. If each farmer set $P_i = P$, relative prices would be constant, but the aggregate price level (and hence real output) would be indeterminate.

previous menu-cost papers measure nominal rigidity. The condition for nonadjustment to be an equilibrium is that a representative farmer i chooses not to pay the menu cost if no other farmer pays. If farmer i maintains a rigid price along with the others, then $D_i = 0$. $P_i = P = 1$, which implies $M/P = M$, and using (11), $P_i/P_i^* = 1/M^{1-\phi}$. Thus, the farmer's utility is $V(M, 1/M^{1-\phi})$.

If farmer i pays the menu cost despite others' nonadjustment, then $D_i = 1$. Adjustment of one price does not affect the aggregate price level, so $P = 1$ and $M/P = M$. Adjustment allows farmer i to set $P_i = P_i^*$, so $P_i/P_i^* = 1$. Thus, farmer i 's utility is $V(M, 1) - z$.

These results imply that the representative farmer chooses not to pay the menu cost—and thus that rigidity is an equilibrium—if

$$(13) \quad G_N < z$$

$$G_N \equiv V(M, 1) - V\left(M, \frac{1}{M^{1-\phi}}\right).$$

G_N is the gain to a farmer from adjusting, given that others do not adjust. Rigidity is an equilibrium if G_N is less than the menu cost.

Taking a second-order approximation of G_N around $M = 1$ yields

$$\begin{aligned} (14) \quad G_N &\cong [V(1, 1) + V_1x + \frac{1}{2}V_{11}x^2] \\ &\quad - [V(1, 1) + V_1x + \frac{1}{2}V_{11}x^2 \\ &\quad + \frac{1}{2}V_{22}(1-\phi)^2x^2] \\ &= \frac{-(1-\phi)^2}{2}V_{22}x^2 \end{aligned}$$

where $x \equiv M - 1$ and where subscripts of V denote partial derivatives evaluated at $(1, 1)$ (recall that V_{22} is negative). The derivation uses the fact that $V_2(M/P, 1) = 0 \forall M/P$, which implies $V_2(1, 1) = V_{12}(1, 1) = 0$. Equation (14) shows that the gain from adjusting is increasing in the size of the shock. Equations (13) and (14) imply that the gain is less

than the menu cost, and so rigidity is an equilibrium, if $|x| < x_N$, where

$$(15) \quad x_N = \sqrt{\frac{-2z}{(1-\phi)^2 V_{22}}}$$

We now ask when price flexibility is an equilibrium. This occurs when farmer i chooses to pay the menu cost if all others pay. If all other farmers pay the menu cost, then $P = M$, so $M/P = 1$. If farmer i pays as well, then $D_i = 1$ and $P_i/P_i^* = 1$; thus, his utility is $V(1, 1) - z$. If farmer i does not pay the menu cost even though others do, then $D_i = 0$, $P_i = 1$, and, using (11), $P_i/P_i^* = 1/M$. In this case, farmer i 's utility is $V(1, 1/M)$.

These results show that farmer i pays the menu cost if

$$(16) \quad G_A > z$$

$$G_A \equiv V(1, 1) - V\left(1, \frac{1}{M}\right).$$

Flexibility is an equilibrium if G_A , the gain from adjusting given that others adjust as well, is greater than the menu cost. A second-order approximation yields

$$(17) \quad G_A = -\frac{1}{2}V_{22}x^2.$$

Like G_N , G_A is increasing in the size of the shock. Equations (16) and (17) imply that flexibility is an equilibrium if $|x| > x_A$, where

$$(18) \quad x_A = \sqrt{\frac{-2z}{V_{22}}}.$$

Combining (15) and (18) yields our central result:

$$(19) \quad \frac{x_N}{x_A} = \frac{1}{1-\phi}$$

in which ϕ , the elasticity of P_i^* with respect to P , is between 0 and 1. Thus, $x_A < x_N$. If

$|x|$ is between x_A and x_N , then both rigidity and flexibility are equilibria.^{7,8}

These results can be summarized as follows. For small monetary shocks ($|x| < x_A$), each farmer refuses to pay the menu cost regardless of others' decisions, and so rigidity is the only equilibrium. For large shocks ($|x| > x_N$), each farmer pays regardless of others, and so flexibility is the only equilibrium. However, for shocks of intermediate size ($x_A < |x| < x_N$), a farmer pays if and only if others do. The reason is that a farmer's gain from adjusting his price is greater if others adjust: G_A is greater than G_N . In Cooper and John's (1988) terminology, there is "strategic complementarity" in price adjustment. To see why, consider a positive shock for concreteness and recall that a farmer's utility-maximizing price, P_i^* , equals $P^\phi M^{1-\phi}$. If others keep their prices fixed at 1, P_i^* rises to $M^{1-\phi}$. However, if others adjust, P rises to M and P_i^* rises to $M > M^{1-\phi}$. That is, if others adjust, they change their prices in the same direction as the money supply, which pushes P_i^* farther from 1. Since the desired increase in P_i is larger, the incentive to adjust is larger.⁹

⁷One can show that, when both rigidity and flexibility are equilibria, there is a third equilibrium in which some farmers adjust and others do not and in which each farmer is indifferent about whether to adjust. This equilibrium is unstable: if slightly more than the required proportion of farmers adjust, then all farmers wish to adjust; if slightly fewer adjust, then none wishes to adjust.

⁸Our result that the model possesses multiple equilibria for some values of x does not appear to depend on our use of Taylor approximations. As explained below, the crucial condition for multiple equilibria is $G_A > G_N$. Without approximating, we are not able to show analytically that this holds for all parameter values, but extensive numerical calculations suggest that it does.

⁹Accommodating monetary policy would be another source of multiple equilibria. Suppose the money-supply rule is changed from $M = 1 + x$ to $M = 1 + c(P - 1) + x$, $0 < c < 1$. Since $P = 1$ if prices are rigid, x_N is not affected; but if prices are flexible, the equilibrium level of P and M is $1 + [x/(1-c)]$ rather than $1 + x$. As a result, $x_A = \{[-2z(1-c)^2]/V_{22}\}^{1/2}$ and $x_N/x_A = 1/[(1-\phi)(1-c)]$. Thus, accommodating monetary policy increases the range of multiple equilibria and makes multiple equilibria possible even if $\phi \leq 0$. Intuitively, accommodating policy creates an ad-

As this discussion suggests, strategic complementarity in price adjustment is tied to a simpler kind of strategic complementarity: the positive dependence of a farmer's utility-maximizing price in the absence of menu costs on the prices of others. The degree to which G_A exceeds G_N depends on ϕ , the elasticity of P_i^* with respect to P [see (14) and (17)].¹⁰ This implies that x_N/x_A is also increasing in ϕ [see (19)]. With strong strategic complementarity— ϕ close to 1—the range of multiple equilibria can be very large. Intuitively, changes in others' prices have a large effect on farmer i 's adjustment decision when they have a large effect on the farmer's desired price.¹¹

So far, our results concern equilibrium responses to a single shock. Now suppose that farmers face a distribution of shocks and choose rules for when to pay the menu cost. We restrict attention to equilibria in which all farmers pay the menu cost if $|x|$ is greater than a cutoff, x^* , that is, if the

money supply lies outside of $(1 - x^*, 1 + x^*)$. The cutoff x^* is a natural measure of the degree of rigidity. Our results imply that any value of x^* between x_A and x_N is an equilibrium; a farmer will adopt any value in this range as a cutoff if all others do. Thus, there is a continuum of equilibrium degrees of nominal rigidity.¹²

Finally, we note an unrealistic feature of our model: since complete adjustment of prices is a unique equilibrium when $|x| > x_N$, very large nominal shocks are necessarily neutral. In practice, large shocks appear to have large real effects; for example, sharp monetary contractions appear to cause deep recessions. Our result is an artifact of the simple static specification. As explained below, it disappears in dynamic versions of the model.

B. Welfare

Many coordination-failure models possess multiple equilibria that can be Pareto ranked. In particular, high-“effort” equilibria (for example, those with high levels of production) are often superior to low-effort equilibria. It is natural to ask whether this is the case in the current model. When there are multiple equilibria in the degree of price rigidity, is less rigidity (more effort expended on price adjustment) better?

To study welfare, we again assume that farmers face a distribution for the monetary shock, x , and pay the menu cost if $|x|$ exceeds a cutoff, x^* . For a symmetric distribution with mean zero, we derive the socially optimal value of x^* : the one that maximizes farmers' expected utility. To determine the welfare properties of equilibrium rigidity, we compare the optimal x^* to x_A and x_N , the endpoints of the range of equilibria. We continue to assume that farmers initially set their prices to 1, the equilibrium value in the absence of shocks; in the Appendix, we study the case in which

ditional source of strategic complementarity: when others raise their prices, M rises, which raises P_i^* .

¹⁰While the result that a farmer's utility-maximizing price increases with others' prices is clearly realistic, one can find cases in which it does not hold. For example, ϕ can be negative (prices can be strategic substitutes) if aggregate demand increases more than one-for-one with real money (as in Ball [1987]). If ϕ is negative, there is always a unique equilibrium in the fraction of farmers who adjust their prices.

¹¹In terms of the model, ϕ approaches 1 as γ approaches 1 (constant marginal utility of leisure) and as ϵ approaches infinity (a perfectly competitive product market). When γ approaches 1, if others do not change their prices, farmer i has no desire to change his: G_N approaches 0 and x_N approaches infinity. However, if others adjust, the benefits of adjusting with them are positive, and so the farmer adjusts if the shock is large enough: x_A approaches $\sqrt{2z/(\epsilon-1)}$. Thus, there are two equilibria for any

$$|x| > \sqrt{2z/(\epsilon-1)}.$$

On the other hand, if ϵ approaches infinity, then G_N approaches infinity and x_N approaches 0 (x_N/x_A still approaches infinity, because x_A approaches 0 more quickly than does x_N). When markets are competitive, a farmer's desired price change is small if others' prices are rigid, but the cost of forgoing even a small change is large. Formally, G_N approaches infinity because V_{22} grows more quickly than $(1-\phi)^2$ shrinks [see (14)].

¹²The economy also possesses equilibria with less natural rules for when to change prices. For example, the set of realizations of M for which prices are rigid can be an asymmetric range, $(1 - x_1^*, 1 + x_2^*)$, or even a disconnected set, $((M_1^*, M_2^*), (M_3^*, M_4^*))$.

initial prices are chosen optimally given the distribution of shocks.¹³

Recall that a farmer's utility is $V(1, 1) - z$ if all farmers pay the menu cost and $V(M, 1/M^{1-\phi})$ if none pays. Thus, since all pay if $|x| > x^*$, expected utility is

$$(20) \quad E[U_i] \\ = \{1 - [F(1 + x^*) - F(1 - x^*)]\} \\ \times [V(1, 1) - z] \\ + \int_{M=1-x^*}^{1+x^*} V\left(M, \frac{1}{M^{1-\phi}}\right) f(M) dM$$

where $F(\cdot)$ is the cumulative distribution function for M and $f(\cdot)$ is the density function. The first-order condition for the socially optimal x^* , denoted x_S , is

$$(21) \quad -2[V(1, 1) - z] \\ + V\left(1 + x_S, \frac{1}{(1 + x_S)^{1-\phi}}\right) \\ + V\left(1 - x_S, \frac{1}{(1 - x_S)^{1-\phi}}\right) = 0$$

where we use the fact that $f(1 + x) = f(1 - x)$ by our assumption that $f(\cdot)$ is symmetric around 1. A second-order approximation leads to

$$(22) \quad x_S = \sqrt{\frac{-2z}{V_{11} + (1 - \phi)^2 V_{22}}}$$

Our central welfare result follows from substituting the appropriate derivatives of

$V(\cdot)$ into (22) and the expressions for x_N and x_A :

$$(23) \quad x_A < x_S < x_N$$

Since $x_S < x_N$, there is a range of equilibrium values of x^* ($x_S < x^* < x_N$) with too much rigidity; in these equilibria, all farmers would be better off if the cutoff were lowered. Since $x_S > x_A$, there is a range of equilibria with too much flexibility. Finally, the social optimum ($x^* = x_S$) is always an equilibrium.

The reason that too much rigidity is possible is similar to the reason in Ball and Romer (1989a). Suppose that all farmers start with an arbitrary x^* . If one farmer lowers his cutoff while the others do not, the only benefit is that he sets $P_i = P_i^*$ more frequently; but if *all* farmers reduce x^* , there is an additional benefit. All prices adjust more frequently, and so the aggregate price level becomes more flexible. This reduces fluctuations in the real money stock and thus stabilizes the demand curves that farmers face. As explained above, farmers prefer stable demand because the disutility of labor is convex. Since the incentive for an individual to reduce x^* is smaller than the gain if all do, values of x^* above x_S can be equilibria.

Values of x^* below x_S can be equilibria (i.e., there can be too much flexibility) because a farmer's gain from raising x^* is also smaller if he does so by himself than if all do. If the others do not join the farmer in raising x^* , then for some shocks he does not adjust his price but others do. Others' adjustment increases movements in P_i^* , which raises the farmer's loss from nonadjustment. (Others' adjustment still benefits the farmer by stabilizing demand, but this effect is smaller.)

While both excessive rigidity and excessive flexibility are possible, the magnitudes of the losses are very different. Neglecting the menu cost, full flexibility is optimal ($x_S = 0$ when $z = 0$). Thus, the net loss from too much flexibility is bounded by the menu cost, which realistically is small. In contrast, Ball and Romer (1989a) show that the loss from too much rigidity can be arbitrarily

¹³We study average welfare given a distribution of shocks because the welfare effect of rigidity after an individual shock depends on the sign of the shock (Mankiw, 1985; Ball and Romer, 1989a). Nonadjustment to a fall in the money supply reduces output and welfare. However, nonadjustment to a positive shock increases output. This raises welfare because, under imperfect competition, the no-shock level of output is too low.

large. Intuitively, the private incentive to reduce x^* —the gain from keeping P_i closer to P_i^* —can be very small because a farmer's utility is insensitive to his relative price over a significant range. Thus, a small menu cost can produce a large x^* even if the resulting fluctuations in real output are highly inefficient. While excessive price flexibility is not likely to be an important problem, excessive rigidity may be.

III. Extensions

A. Heterogeneous Agents

In our basic model, multiple equilibria arise when each farmer chooses to adjust his price if and only if others do. The desire to make the same decision as others is crucial. A natural question is whether multiple equilibria are possible if heterogeneity leads some agents to adjust while others do not. Here we show that models with heterogeneity can possess multiple equilibria in the proportion of prices that adjust and, therefore, in the size of the real effects of a nominal shock. We focus on heterogeneity in the size of menu costs, which is the simplest case. Strategic complementarity is necessary for multiple equilibria; the sufficient condition depends on the distribution of the menu cost. Other sources of heterogeneity lead to similar results.

Assume that the menu cost, z , varies across farmers with cumulative distribution function $H(z)$. After a shock, farmers with z below some critical level adjust their prices, and the others do not. Let k be the proportion that adjust. We derive an equilibrium condition for k .

Let $P_A(x, k)$ be the price set by those who adjust and let $P(x, k)$ be the aggregate price level. Note that $P_A = P_i^* = P^\phi(1+x)^{1-\phi}$ and [approximating (6)] $P \cong kP_A + (1-k)$. These relations imply

$$(24) \quad P_A(x, k) \cong 1 + \frac{1-\phi}{1-\phi k} x.$$

By reasoning similar to that in Section II,

the gain from adjusting is

$$(25) \quad G(x, k) = V\left(\frac{1+x}{P(x, k)}, 1\right) - V\left(\frac{1+x}{P(x, k)}, \frac{1}{P(x, k)^\phi(1+x)^{1-\phi}}\right).$$

Using (24) and (25), one can show that

$$(26) \quad G(x, k) \cong -\frac{1}{2} \left(\frac{1-\phi}{1-\phi k} \right)^2 V_{22} x^2.$$

The crucial result is

$$(27) \quad \frac{\partial G(x, k)}{\partial k} > 0.$$

The gain from adjusting is increasing in the proportion of firms that adjust. This is a generalization of the earlier result that the gains are greater when all adjust than when none adjusts. Again, adjustment by others moves the price level in the same direction as the money supply, which increases the deviation of P_i^* from 1.

A farmer pays his menu cost if it is less than $G(x, k)$. Thus, the proportion who pay is $H(G(x, k))$, and an equilibrium k is one that satisfies $k = H(G(x, k))$. A necessary condition for multiple equilibria is $\partial H(G(x, k))/\partial k > 0$ over some range. Since $\partial H(G(x, k))/\partial k = dH/dG \cdot \partial G/\partial k$ and $H(\cdot)$ is increasing over some range, the condition reduces to (27), which holds because of strategic complementarity. The sufficient condition depends on the size of x and the shape of $H(\cdot)$; it is easy to find examples both of multiple equilibria and of unique equilibria.¹⁴

¹⁴Introducing heterogeneous real shocks leads to similar results. Suppose that the production function (3) is replaced by $Y_i = \theta_i L_i$, that θ_i varies across farmers, and that a shock to θ_i occurs at the same time as the monetary shock. Farmer i will choose to pay the menu cost if θ_i is above an upper cutoff or below a lower cutoff; both critical values depend on x and k . Again, one can show that multiple equilibria are possible and that strategic complementarity is a necessary condition.

Our results again parallel others in the coordination-failure literature. Diamond (1982), for example, introduces heterogeneity in the costs of production opportunities. Greater aggregate production raises an agent's incentive to produce by creating more trading partners. This strategic complementarity can produce multiple equilibria in the proportion of opportunities undertaken. As in our model, sufficient conditions depend on the distribution of costs.

B. Dynamics

So far we have studied a static model. In reality, price rigidity is a failure of prices to adjust quickly over time. Therefore, we now consider a dynamic version of our model. We focus on an example in which farmers choose between adjusting prices every period and adjusting every two periods; at the end, we briefly consider more general cases. There are two results. First, strategic complementarity in optimal prices produces multiple equilibria in the frequency of adjustment and hence in the dynamics of real output. Second, in contrast to other coordination-failure models, the economy converges to a unique long-run equilibrium.

Assume that the money stock follows a random walk; its innovations have mean zero and variance σ_m^2 . A farmer can adjust his price every period or every two periods, and he pays a menu cost z for each adjustment. When a farmer adjusts, he does so after observing the current money stock. If he adjusts every period, he always sets $P_i = P_i^*$. If farmers adjust every two periods, they all adjust in even periods; that is, price-setting is synchronized (Gary Fethke and Andrew Policano [1984] and Ball and Romer [1989b] show that this is the equilibrium timing when all shocks are aggregate). In this case, since M is a random walk, in even periods farmers set $P_i = P_i^* = M$; in odd periods, prices do not adjust to the most recent change in M .^{15,16}

¹⁵When prices are set for two periods, a farmer's optimal price in fact differs slightly from the first-period value of M , because this is not the optimal rigid price for the second period: as in the static model, certainty

We assume that each farmer chooses his frequency of adjustment taking others' frequency as given and solve for Nash equilibria. This exercise is a simple extension of the static case. A farmer compares the added cost of adjusting in odd periods to the expected gain from keeping $P_i = P_i^*$ in odd periods, which depends on others' frequency of adjustment. One can show that adjustment only in even periods is an equilibrium if

$$(28) \quad \frac{-(1-\phi)^2}{2} V_{22} \sigma_m^2 < z$$

and adjustment every period is an equilibrium if

$$(29) \quad -\frac{1}{2} V_{22} \sigma_m^2 > z$$

where we use approximations analogous to (14) and (17). Conditions (28) and (29) are the same as the conditions for nonadjustment and adjustment in the static model except that x^2 , the square of a given shock, is replaced by σ_m^2 , the *expected* square of the shock. The reason is that farmers decide how frequently to adjust before observing the realizations of shocks.

Since $0 < \phi < 1$, there are multiple equilibria in price adjustment for a range of z (or, for given z , for a range of σ_m^2). This multiplicity implies multiple equilibria in output dynamics. If prices adjust every period, monetary shocks are neutral, and output is constant. If prices adjust only in even periods, shocks in odd periods cause output movements that last until the next adjustment. In contrast to our static model, the

equivalence fails. Allowing farmers to choose prices different from the initial M introduces complications similar to the ones for the static model (see the Appendix).

¹⁶Rather than adjust every period, a farmer could guarantee $P_i = P_i^*$ by adjusting every two periods (or never) but indexing his price to the money stock. Thus, an alternative interpretation of the model is that a farmer chooses between setting a noncontingent price for two periods and setting an indexed price. Under this interpretation, z is an indexation cost.

output effect of an odd-period shock is strictly increasing in the size of the shock.¹⁷

Strategic complementarity is again the source of multiple equilibria. Intuitively, more frequent adjustment by others makes the price level respond more quickly to shocks and thus makes it more volatile. For $\phi > 0$, greater volatility in the price level implies greater volatility in a farmer's desired price, which increases his incentive to adjust frequently. For some parameter values, the incentive to adjust every period exceeds the added cost if and only if others adjust every period.

While we focus here on a simple example, the central results carry over to more general settings. An earlier version of this paper (Ball and Romer, 1988) considers a continuous-time model in which farmers can choose any frequency of adjustment. Strategic complementarity in desired prices can lead to multiple equilibria in the frequency. This implies multiple equilibria in the adjustment speed of the aggregate price level and hence in the path of output following a shock. Sufficient conditions for multiple equilibria depend on how steeply the costs of price adjustment increase with the frequency of adjustment.

Finally, our dynamic model makes clear a difference between coordination failure in price adjustment and coordination failures identified by previous authors. In previous models, there is no reason for an economy in a Pareto-dominated equilibrium to leave it. For example, if each agent in the Diamond model does not produce because others do not produce, this situation need not improve over time. In contrast, our model implies differences between the short-run and long-run behavior of the economy. Multiple equilibria in the frequency of price adjustment imply multiple equilibria in the

size and duration of the output effects of nominal shocks. However, there is a unique long-run response to a shock: prices eventually adjust fully, and the shock is neutral.¹⁸

IV. Conclusions and Implications

This paper shows that nominal price rigidity can arise from a failure of firms to coordinate price changes. Increases in price flexibility by different firms are strategic complements: greater flexibility of one firm's price raises the incentives for other firms to make their prices more flexible. Strategic complementarity can lead to multiple equilibria in the degree of nominal rigidity, and welfare may be much higher in the low-rigidity equilibria. Thus, the inefficient economic fluctuations resulting from nominal shocks might be greatly reduced if agents could "agree" to move to a superior equilibrium.

We conclude by discussing the empirical and policy implications of our results. One implication is that there can be considerable variation across economies in the degree of nominal rigidity and hence in the size of real fluctuations, without large variation in the underlying determinants of rigidity. Multiple equilibria imply that differences in rigidity can arise without any underlying differences. Even with unique equilibria, strategic complementarity implies that there is a "multiplier" (Cooper and John, 1988): small underlying differences can lead to large differences in rigidity. Nominal rigidity does in fact appear to vary considerably across countries; for example, Dennis Grubb et al. (1983) estimate that the adjustment of nominal wages to inflation is more than three times as fast in the average Western European country as in the United States. It could be a mistake to search for explanations of such differences based on the un-

¹⁷The result that money matters in odd but not even periods is unattractive, but it can be eliminated through realistic modifications of the model. For example, if idiosyncratic productivity or demand shocks arrive at different times for different farmers, then there can be an equilibrium with staggered adjustment: half of all prices change every period (Ball and Romer, 1989b). In this case, the effect of a shock does not depend on when it occurs, and the shock's real effects are strictly increasing in its size.

¹⁸If we modified the model so that the short-run response of the economy had permanent effects, through either capital accumulation or more exotic "hysteresis" mechanisms (Blanchard and Lawrence Summers, 1986), then the economy would no longer have a unique long-run equilibrium. Even in this case, however, there would be a unique long-run degree of price rigidity (full flexibility).

derlying natures of economies. Perhaps the apparent importance of unexplained "institutions" simply reflects the fact that different economies settle at different equilibria.

Another set of empirical implications arises if we ask why an economy arrives at one equilibrium rather than another. Current coordination-failure models generally do not address this subject, but a natural possibility is that the selection of an equilibrium is determined by history (Howard Naish, 1987; Lawrence Summers, 1987). For concreteness, consider the institutions governing wage-setting, such as the presence or absence of indexation. It appears natural to assume that these arrangements do not change with changing economic conditions as long as existing institutions continue to be among the set of equilibria. With this additional assumption, our model suggests that differences in wage-setting across similar economies can be explained by differences in past conditions; differences in past inflation variability, for example, might account for differences in the prevalence of indexation. It does not appear difficult to test for such an effect of history. One might, for example, regress a cross-country measure of the extent of indexation on current and historical variables.

Our results also add to the implications of menu-cost models for microeconomic data. One can test directly for strategic complementarity with data on the lengths of labor contracts or the frequency of changes in individual prices. The natural approach is to estimate the relation across countries or time periods between the frequency of an individual firm's wage or price adjustment and the average frequency in the economy. (Of course, there is an identification problem, since one firm's frequency could respond to the same unobservable variables as others' frequency; one would need to find instruments.) Such a test would be in the spirit of Aloysius Siow (1987), who uses microeconomic data to test for strategic complementarity in individuals' hours of work.

The result in previous papers that equilibrium rigidity can be excessive suggests a role for government regulation of price-set-

ting, such as restrictions on the lengths of labor contracts. This paper's results strengthen this policy implication in several ways. First, with multiple equilibria, policy can be less coercive. Instead of prohibiting certain contract provisions, the government could simply convene meetings of business and labor leaders to coordinate adjustment (as some European governments appear to do). Second, by moving the economy to a new equilibrium, temporary regulations can permanently change the degree of nominal rigidity. There is evidence of such effects: Stephen Cecchetti (1987) finds that the Nixon wage-price controls have permanently altered the provisions of U.S. labor contracts. Third, the multiplier arising from strategic complementarity magnifies the effects of policy. Regulation of union contracts would directly affect only a small fraction of wages in the United States. However, more flexible union wages would increase the incentives for wage and price flexibility throughout the economy and thus could have large effects on overall flexibility.

Finally, if coordination of wage and price adjustment proves difficult, an alternative is to substitute active monetary policy. In the *General Theory*, John Maynard Keynes (1936 pp. 266-8) argued that it is easier for the government to offset a fall in demand by increasing the money stock than for decentralized agents to reduce nominal wages in tandem. As Summers (1987) points out, governments adjust schedules through daylight saving time because it is difficult for decentralized agents to coordinate on a desirable equilibrium. Perhaps governments should be responsible for offsetting macroeconomic shocks for similar reasons.

APPENDIX

This appendix relaxes the assumption of our static model that all prices equal 1 before the monetary shock occurs. We assume instead that farmers choose initial prices optimally and show how this affects our results. The analysis draws heavily on Ball and Romer (1989a). As in that paper, we assume that the distribution of the monetary shock is symmetric around zero, single-peaked, and continuous.

The price that a farmer sets before observing the money supply depends on others' initial prices and on the value of the cutoff x^* . In symmetric equilibrium, each farmer's initial price is

$$(A1) \quad P_0(x^*) \cong 1 + \frac{\gamma}{2} \hat{\sigma}_M^2(x^*)$$

where $\hat{\sigma}_M^2(x^*)$ is the variance of M conditional on $1 - x^* < M < 1 + x^*$ (see Ball and Romer, 1989a). Given our use of second-order approximations, assuming initial prices equal to P_0 rather than 1 does not affect our results about equilibrium rigidity: the expressions for x_N and x_A in the text remain valid (Ball and Romer [1989a] shows this for x_N). We now show, however, that the socially optimal degree of rigidity changes slightly.

If initial prices are P_0 and prices are rigid, then $M/P = M/P_0$ and $P_i/P_i^* = P_0^{1-\phi}/M^{1-\phi}$. Thus, when initial prices are set optimally, a farmer's expected utility, (20), becomes

(A2)

$$E[U_i] = \{1 - [F(1+x^*) - F(1-x^*)]\} [V(1,1) - z] + \int_{m=1-x^*}^{1+x^*} V\left(\frac{M}{P_0(x^*)}, \frac{[P_0(x^*)]^{1-\phi}}{M^{1-\phi}}\right) f(M) dM.$$

The first-order condition for x_S is

$$(A3) \quad -[f(1-x_S) + f(1+x_S)][V(1,1) - z] + f(1-x_S)V\left(\frac{1-x_S}{P_0(x_S)}, \frac{[P_0(x_S)]^{1-\phi}}{(1-x_S)^{1-\phi}}\right) + f(1+x_S)V\left(\frac{1+x_S}{P_0(x_S)}, \frac{[P_0(x_S)]^{1-\phi}}{(1+x_S)^{1-\phi}}\right) + \left\{ \int_{M=1-x_S}^{1+x_S} \left[V_1\left(\frac{M}{P_0(x_S)}, \frac{[P_0(x_S)]^{1-\phi}}{M^{1-\phi}}\right) \times \left(\frac{-M}{[P_0(x_S)]^2}\right) + V_2\left(\frac{M}{P_0(x_S)}, \frac{[P_0(x_S)]^{1-\phi}}{M^{1-\phi}}\right) \times \left(\frac{(1-\phi)[P_0(x_S)]^{-\phi}}{M^{1-\phi}}\right) \right] f(M) dM \right\} \times P'_0(x_S) = 0$$

where $P'_0 \equiv (\partial P_0 / \partial x^*)$. Taking a second-order approximation and substituting (A1) for P_0 yields

$$(A4) \quad -[f(1-x_S) + f(1+x_S)] \times [V(1,1) - z] + f(1-x_S) \times \{V(1,1) + V_1[-x_S - (\gamma/2)\hat{\sigma}_M^2] + (1/2)V_{11}x_S^2 + (1/2)V_{22}(1-\phi)^2x_S^2\} + f(1+x_S)\{V(1,1) + V_1[x_S - (\gamma/2)\hat{\sigma}_M^2] + (1/2)V_{11}x_S^2 + (1/2)V_{22}(1-\phi)^2x_S^2\} - (\gamma/2)V_1[f(1+x_S) + f(1-x_S)] \times (x_S^2 - \hat{\sigma}_M^2) = 0.$$

Finally, using the fact that $f(1+x) = f(1-x)$, the solution for x_S is

$$(A5) \quad x_S \cong \sqrt{\frac{-2z}{V_{11} + (1-\phi)^2V_{22} - \gamma V_1}}$$

Substituting the derivatives of $V(\cdot)$ into (A5) establishes that $x_S < x_N$ and that x_S can be either greater or less than x_A . The possibility of $x_S < x_A$, which implies that all equilibria possess too much rigidity, is the main departure of these results from the ones in the text. The explanation is that P_0 , the price level under rigidity, is greater than 1, its level in the text. Thus, average output under rigidity is lower than in the text, which makes it more likely that reducing rigidity would increase welfare.

When Excessive Consumption Is Rational

By RICHARD E. ROMANO*

If average cost is everywhere above market demand, it is usually argued that the nondiscriminating firm will shut down, although the first-best outcome may dictate production. In this setting, it is shown that there is often a Nash equilibrium in consumption that will keep the firm producing. Selfish consumers engage in excessive (beyond demand) consumption to keep the firm in business and to protect their surpluses. This is shown to be true in a simple model with perfect information and also in a more realistic model in which consumers are uncertain about the firm's costs. (JEL L10, D80)

"You [resident of Lake Wobegon] need a toaster, you buy it at Co-op Hardware even though you can get a deluxe model with all the toaster attachments for less money at K-Mart in St. Cloud."

[Garrison Keillor, 1985 pp. 95-6]

Have you "small towners" ever found yourselves in the following type of situation? A new restaurant opens that has an unusual menu but one that well suits your preferences. You suspect the local demand to be slack and fear for the restaurant's survival. You contemplate more frequent patronage than you would if you were certain that the place would not fail.

This paper shows that such behavior can be rational. It can be optimal to consume in excess of that indicated by one's demand curve, derived under standard conditions, in particular when it is believed that one can purchase all that is desired over the market period. This "excessive consumption" has nothing to do with altruism. It can be a part of a Nash equilibrium in consumption with

selfish consumers. Though Keillor attributes the behavior described in the above quotation to social-mindedness, I will offer a competing explanation.

The logic of the result is the following. There is an incentive to consume beyond demand to protect one's surplus when nonexcessive consumption may be insufficient to keep a firm producing. Keeping the firm in business is a public good, so that there is a countervailing incentive to free ride on others' excessive consumption. If consumers know the firm's costs, then they know exactly the level of consumption that is necessary to keep the firm producing; and the incentive to free ride is resolved in a Nash consumption equilibrium. If consumers are uncertain about the firm's costs but fear that the firm may go out of business, free riding may not be perfectly resolved in Nash equilibrium, although there is still excessive consumption. Since excessive consumption is voluntary, it obviously will result in improved efficiency.

I. The Certain Case

A. An Example

A simple example illustrates an excessive-consumption equilibrium and highlights the issues. The example is illustrated in Figure 1. Consider a market with two identical consumers who have demands $d_i = \frac{1}{2}(a - p)$, $i = 1, 2$, so that market demand is given by $d = a - p$. There is a single firm with cost

FIGURE 2. TIMING OF THE TWO-STAGE, ONE-PERIOD GAME PLAYED BY CONSUMERS AND THE FIRM

expressed consumption levels are inadequate; and, likewise, the firm anticipates the resulting Nash consumption levels when it sets price. I analyze a kind of "subscription equilibrium," where no consumption takes place unless the subscribed consumption levels are sufficiently large. An alternative would be to analyze a repeated game.¹ The present rendition is simple in that it permits analysis of a one-period game.

The Results.—The first proposition regards equilibrium in the consumption stage of the game. Assumption 1 is adopted in the three propositions of this subsection.

PROPOSITION 1: (a) $q^* = (q_1^*, q_2^*, \dots, q_n^*)$ is a Nash equilibrium with positive consumption if and only if (i) $q_i^* \geq d_i(p)$, (ii) $CS_i \geq 0$, and (iii) $\Pi(p, \Sigma q_i^*) = 0$. (b) In any Nash equilibrium with positive consumption, at least one consumer engages in excessive consumption [i.e., $q_i^* > d_i(p)$ for some i].

PROOF:

(a) Consider first the necessity of (i)–(iii). If $q_i^* < d_i(p)$, then q_i^* is not a best response. Likewise, if $CS_i < 0$, then q_i^* is not a best response. Regarding the necessity of (iii), if $\Pi < 0$, then positive consumption will not result. If $\Pi > 0$, then $q_i^* > d_i(p)$ for some i by Assumption 1, and that consumer could reduce consumption without causing $\Pi < 0$ and thereby could increase CS_i . Hence, $\Pi = 0$ is also necessary. Sufficiency of (i)–(iii) follows from the fact that no consumer gains by deviating from q_i^* . Increasing q_i lowers CS_i by (i). Decreasing q_i causes the firm not to produce by (iii), and the consumer would sacrifice CS_i .

(b) $q_i^* > d_i(p)$ for some i or, otherwise, (iii) and Assumption 1 are inconsistent.

An interesting characteristic of an excessive-consumption equilibrium is that, even though there are externalities in consumption (all consumers would lose if one reduces consumption from equilibrium), free riding is controlled. The situation provides a natural and harsh punishment to such deviations in the form of exit and lost consumer surplus.² Consumers are willing to engage in excessive consumption to protect the surplus obtained on the units below ordinary demand. If price is such that there exists an excessive-consumption equilibrium, there is an infinite number of such equilibria (excepting the boundary case in which $CS_i = 0$ for all i in equilibrium). To see this, suppose that q^* is an excessive-consumption equilibrium with elements (q_i^*, q_j^*) , $CS_i > 0$, and $q_j^* > d_j$. Then, the modified vector of consumption levels with elements $(q_i^* + \varepsilon; q_j^* - \varepsilon)$ is another excessive-consumption equilibrium. Note that the aggregate consumption level is constant across such equilibria.

In addition, there are, in general, trivial equilibria with zero consumption. Such equilibria are Pareto inferior to equilibria with positive consumption, and they will be ignored in what follows.³ This leads to the

²These Nash equilibria in consumption are similar to those obtained in Bengt Holmstrom's (1982 p. 327) theorem 2. Likewise, they resemble the equilibria that arise in the literature on the voluntary provision of discrete public goods (Thomas R. Palfrey and Howard Rosenthal, 1984; Mark Bagnoli and Barton L. Lipman, 1989). The problem with certain costs provides a natural example of the voluntary provision of a discrete public good.

³One might also proceed under the assumption that the firm attaches some probability to the occurrence of a "zero-consumption equilibrium" when pricing. This would not change the results in this section (see footnote 7, below, regarding the next section), since profits are zero in such an equilibrium and also in an equilibrium with positive consumption.

¹A longer version of this paper discusses this and other extensions. Contact the author for a copy.

determination of price, which is the topic of Proposition 2.

PROPOSITION 2: *The firm is indifferent over its choice of price.*

PROOF:

This follows immediately from the fact that profits equal zero in any excessive-consumption equilibrium.

There will generally be a range of prices that support excessive-consumption equilibria, and the firm is indifferent among these. Since profits equal zero in equilibrium, the firm is also indifferent about entering. This bothersome result will not be true in the more realistic case examined in the next section.

An excessive-consumption equilibrium is obviously Pareto superior to the firm not entering. It is also obvious that there must be positive net surplus at the first-best consumption/output vector for there to exist an excessive-consumption equilibrium. This is also sufficient for the existence of equilibrium if consumers have identical preferences, but it is not otherwise. Proposition 3 formalizes these results and presents the necessary and sufficient condition under which an excessive-consumption equilibrium exists. Two definitions are useful. Let $q_i^f \equiv d_i^{-1}(c)$, so that $\mathbf{q}^f = (q_1^f, q_2^f, \dots, q_n^f)$ is the first-best consumption vector. Define $\bar{q}_i(p)$ implicitly in $CS_i(p, \bar{q}_i) = 0$: $\bar{q}_i(p)$ equals the maximum quantity a consumer would ever purchase in an excessive-consumption equilibrium.

PROPOSITION 3: (a) *The condition*

$$(1) \quad \sum CS_i(p, q_i^f) + \Pi(p, \sum q_i^f) \geq 0$$

is necessary for there to exist an excessive-consumption equilibrium. (a') Condition 1 is also sufficient if consumers are identical but is not otherwise. (b) The existence of a p such that

$$(2) \quad (p - c) \sum \bar{q}_i(p) \geq F$$

FIGURE 3. A MARKET WITH TWO CONSUMERS WITH DEMANDS d_1 AND d_2

is necessary and sufficient for there to exist an excessive-consumption equilibrium.

PROOF:

(a) If $\sum CS_i(p, q_i^f) + \Pi(p, \sum q_i^f) < 0$, then there exists no vector \mathbf{q} with some positive consumption levels such that the expression is nonnegative. Hence, it would be impossible to satisfy conditions (ii) and (iii) of Proposition 1 with any positive consumption levels.

(a') Let $\Pi(p^f, \sum q_i^f) = 0$ define p^f . For the case of identical consumers, since $CS_i(p^f, q_i^f) = CS_j(p^f, q_j^f)$ for all i and j , the augmented vector (p^f, \mathbf{q}^f) is easily seen to be an excessive-consumption equilibrium.

A counterexample may be used to show that (1) is not sufficient in the presence of nonidentical consumers. Refer to Figure 3 which depicts a market with two consumers with demands d_1 and d_2 . D is the market demand. Assume that the indicated areas E and H satisfy $E + 2H = F$. Thus, (1) is satisfied with equality, but no excessive-consumption equilibrium exists, as is now argued. Let p_1 satisfy $\Pi(p_1, q_1^f + q_2^f) = 0$, and note that $CS_1(p_1, q_1^f) + CS_2(p_1, q_2^f) + \Pi(p_1, q_1^f + q_2^f) = CS_1(p_1, q_1^f) + CS_2(p_1, q_2^f) = 0$. It is clear from the figure that $CS_2(p_1, q_2^f) > CS_1(p_1, q_1^f)$, and therefore, the latter is negative. This precludes an excessive-consumption equilibrium with the first-best values. Since (1) vanishes, there can be no equilibrium at other than the first-best val-

ues, since the "available surplus" would be negative.

(b) To see necessity of existence of a p such that (2) is satisfied, suppose none exists. Then, the requirement of an excessive-consumption equilibrium that $\Pi = 0$ necessitates $q_i > \bar{q}_i$ for at least one consumer; but such a choice could not be a best response, since this implies $CS_i < 0$.

Sufficiency of the condition is shown by construction. For any p such that (2) is satisfied, there will exist a vector q with $q_i \leq \bar{q}_i(p)$ such that (2) holds with equality. Moreover, there exists such a vector with $q_i \geq d_i(p)$, or else Assumption 1 is contradicted. Any such vector is easily seen to be an excessive-consumption equilibrium.

Proposition 3 indicates that a potential for surplus is enough to guarantee that some surplus can be realized in an excessive-consumption equilibrium, provided consumers have identical preferences. This is not sufficient without identical preferences, because of the following. The model imposes the constraint that every consumer must pay the same per unit of consumption. This implies that every consumer's *average* valuation must not be less than average cost at the first best, if it is to be sustainable as a Nash equilibrium.⁴ Identical preferences are required to ensure this.

⁴Several of my colleagues have suggested that I relate this analysis to the all-or-none demand curve. An individual's all-or-none demand curve shows the maximum price he would be willing to pay to obtain each quantity. There are two ways one might construct a *market* all-or-none demand curve; both assume zero income effects. One construction horizontally sums the individual's all-or-none demand curves. For this construction, there will exist an excessive-consumption equilibrium if and only if the market all-or-none demand curve crosses the average cost curve. Alternatively, using the ordinary market demand curve, one could calculate the total value placed on each market quantity and then relate each quantity to the corresponding average value. This will be the same as the first construction if consumers have identical preferences, but it will otherwise generally be beyond the first construction, because it does not require each consumer to have the same average valuation. It is necessary but not sufficient that the second construction crosses the average cost curve for there to exist an excessive-consumption equilibrium.

With or without identical preferences, the proposition should not be understood to imply that the first best is the compelling outcome. It is worth noting that there can exist an excessive-consumption equilibrium when the first-best consumption vector is not sustainable as a Nash equilibrium.⁵ Moreover, note that there is only one price that could sustain the first-best consumption vector as an equilibrium and yet the firm is indifferent over price.

An excessive-consumption equilibrium has the razor's-edge property that a marginal reduction in consumption by any consumer will cause the firm to exit. This stretches one's imagination, since it is difficult to believe that any consumer in the real world will have enough information to imagine himself on such a precipice. The natural question to ask is whether excessive consumption will persist in a model with a more realistic information structure. The answer is shown to be "yes" in the next section, where F will be unknown to consumers when the Nash consumption game is played. The razor's-edge property of the certainty model is also related to some troubling outcomes of the model. One such outcome is that the model fails to predict both a unique price and consumption pattern because of the two types of multiple equilibria that arise. Also, one finds that the firm is indifferent to entering. The extension will go a long way toward resolving these problems.

II. The Case of Uncertainty About Fixed Costs

To capture consumer uncertainty, I will assume that consumers do not observe the fixed cost in this section. The main results are twofold. Excessive consumption will continue to characterize Nash equilibrium; and under fairly general conditions, equilibrium will be unique. After describing the modifications to the model, the results are described, and an example is presented.

⁵Contact the author for an example of this.

A. Modifications to the Model

The timing is the same as in Figure 2, except that only the firm observes F . The fixed cost is drawn from a continuous probability distribution $G(F)$ with support $[a, b] \in [0, \infty)$. The associated density function g is strictly positive and differentiable in the interior of its support. Further, the following is assumed.

ASSUMPTION 2: *The ratio $g(x)/G(x)$ is nonincreasing in x .*

Assumption 2 is useful in establishing the existence and uniqueness properties of equilibrium. It is satisfied by the set of Polya frequency distributions of order two (see Richard E. Barlow and Frank Proschan, 1965), which is a large set of unimodal densities including (with appropriate restrictions on parameters) the uniform, exponential, beta, gamma, Weibull, normal, and truncated normal distributions. Though consumers will not observe the realization of F , G is assumed to be common knowledge.

Note that $G[(p - c)\sum q_i]$ is the probability that the realization of fixed cost is no greater than revenue minus variable costs, which then equals the probability that the firm produces. The analogous assumption to Assumption 1 here is the following.

ASSUMPTION 1':

$$G[(p_m - c)\sum d_i(p_m)] < 1$$

where p_m is again the usual monopoly price.

Hence, I assume that there is a positive probability that the firm would shut down with monopoly pricing and consumption determined by ordinary demands. A final assumption is as follows.

ASSUMPTION 3:

$$G[(p - c)\sum \bar{q}_i(p)] > 0 \text{ for some } p$$

where, recall, $CS_i(p, \bar{q}_i) = 0$ defines $\bar{q}_i(p)$.

This is analogous to (2) in part (b) of Proposition 3.⁶ Assumptions 1', 2, and 3 are maintained throughout this section. Everything else, including the notation, is the same as in the certainty case.

B. Analysis and Results

Consider first the consumption stage of the game. Consumers will maximize their expected consumer surplus, taking into account their influence on the probability that the firm chooses to produce. The i th consumer chooses $q_i \geq 0$ to maximize the function

$$(3) \quad E[CS_i] = \left(\int_0^{q_i} d_i^{-1}(x) dx - pq_i \right) \times G[(p - c)\sum q_j].$$

Three lemmas are useful.

LEMMA 1: *$E[CS_i]$ is strictly quasi-concave in q_i for all $\sum_{j \neq i} q_j$ and $G > 0$.*

PROOF:

See the Appendix.

LEMMA 2: *For p such that Assumption 3 is satisfied, there exists a Nash equilibrium (in pure strategies) with $G > 0$.*

PROOF:

See the Appendix.

Lemma 2 indicates that there will be a nontrivial equilibrium with a positive probability of production for some prices. There may also exist equilibria with zero probability of resulting production (e.g., the zero consumption vector may be an equilibrium). As in the certainty case, these equilibria will be Pareto inferior to any equilibrium with a positive probability that the firm will produce. I ignore these equilibria in what fol-

⁶Given the other assumptions, Assumption 3 will be necessary and sufficient for the existence of an excessive-consumption equilibrium, though the paper proceeds in a somewhat different order here.

lows.⁷ Note that Lemma 2 implies that there exists an equilibrium with excessive consumption if, for all prices, there is zero probability that the firm would produce with consumption determined by ordinary demand (i.e., if $G[(p_m - c)\sum d_i(p_m)] = 0$). I will show that the weaker Assumption 1' is sufficient for the existence of an equilibrium with excessive consumption.

LEMMA 3: *A Nash consumption equilibrium will never have $(p - c)\sum q_i > b$ (recall that b is the upper bound of the support of F).*

PROOF:

By Assumption 1', an equilibrium with $(p - c)\sum q_i > b$ would require that $q_i > d_i$ for some i . But such a choice could not be a best response. The consumer could always marginally decrease consumption, maintain $G = 1$, and thereby increase utility.

The last obstacle to describing Nash consumption equilibria is to note that the payoff functions in (3) are nondifferentiable in q_i at $(p - c)\sum q_j = b$ if $g(b) > 0$. This leads to the possibility of either an "interior equilibrium" or a "corner equilibrium," which are respectively described by the systems

$$(4a) \quad (d_i^{-1}(q_i^*) - p)G[(p - c)\sum q_j^*] \\ + (p - c)CS_i(p, q_i^*) \\ \times g[(p - c)\sum q_j^*] = 0 \\ i = 1, \dots, n$$

⁷As in the certainty case (see footnote 3), one could also proceed by assuming that the firm attaches some probability to the result of a trivial equilibrium, where such equilibria exist. If it is assumed that this probability is independent of price, which may be reasonable if there exist trivial equilibria at all relevant prices ($p > c$), then the results of this section are unaffected. Alternatively, one might somehow link this probability to some measure of the relative number of such equilibria, in which case the results require some modification. It seems sensible to attach a higher probability to Pareto superior equilibria, and I have chosen to assign a probability of 1 to this set.

$$(4b) \quad a < (p - c)\sum q_j^* < b$$

or

$$(5a)$$

$$d_i^{-1}(q_i^*) - p + (p - c)CS_i(p, q_i^*)g(b) \geq 0 \\ i = 1, \dots, n$$

$$(5b) \quad (p - c)\sum q_j^* = b.$$

In both cases, without loss of generality, I ignore consumers who demand zero of the good at the current price [I assume $d_i(p) > 0$ for all i].

The first proposition of this section describes further the nature of equilibrium and the conditions under which the two types arise and, most importantly, shows the existence of excessive consumption. Its statement is facilitated by defining $\hat{q}_i(p)$ as the value that satisfies

$$(6) \quad d_i^{-1}(\hat{q}_i) - p + (p - c)g(b) \\ \times CS_i(p, \hat{q}_i) = 0.$$

This equals the maximum quantity a consumer would be willing to consume in a Nash equilibrium when it is certain that the firm will produce. Note that $\hat{q}_i \geq d_i$.

PROPOSITION 4: *Assume that price is such that Assumption 3 is satisfied. (a) If $(p - c)\sum \hat{q}_i(p) < b$, then there is a unique Nash equilibrium with a positive probability that the firm will produce. It has $0 < G < 1$, and every consumer engages in excessive consumption. (b) If $(p - c)\sum \hat{q}_i(p) > b$, then there are multiple Nash equilibria with positive probability that the firm produces. Each has $G = 1$ and at least one consumer who engages in excessive consumption.*

PROOF:

See the Appendix.

The corner equilibria in the uncertainty model are similar to the excessive-consump-

tion equilibria that arise in the certainty model. Where one arises, there is an infinite number, each of which entails excessive consumption by a subset of consumers. Proposition 4 indicates that there will either be multiple corner equilibria or a unique interior equilibrium.⁸ The interior equilibrium may, however, be a more "likely" outcome. Before discussing further the properties of an interior equilibrium, the next proposition makes a case for their prevalence.

PROPOSITION 5: *Assume that price is such that Assumption 3 is satisfied. Any of the following conditions implies that an interior equilibrium arises:*

- (a) $\sum CS_i(c, q_i^f) < b$, where $q_i^f \equiv d_i(c)$ is i 's first-best consumption level;
- (b) $g(b) = 0$;
- (c) in a finite economy ($n < \infty$), the range of F exceeds some finite value (that is a function of parameters); in a finite economy, the variance of F exceeds some finite value.

PROOF:

(a) This is shown by demonstrating that there cannot be an equilibrium with $G = 1$. If there were, then from (5b), $(p - c)\sum q_i^* = b$. That $\sum CS_i(c, q_i^f) < b$ implies $\sum CS_i(p, q_i) + (p - c)\sum q_i < b$ for any p and vector q and, in particular, any equilibrium vector q^* . Hence, $\sum CS_i(p, q_i^*) < b - (p - c)\sum q_i^* = 0$. This implies $CS_i(p, q_i^*) < 0$ for some i ; and since $E[CS_i] = CS_i G = CS_i$ here, it implies that some consumer has negative expected consumer surplus in equilibrium. Of course, this cannot happen.

(b) If $g(b) = 0$, then (6) implies $\hat{q}_i = d_i$, and thus Assumption 1' implies $(p - c)\sum \hat{q}_i < b$. Hence, the result follows from part (a) of Proposition 4.

(c) Since $a \geq 0$, b eventually increases without bound as the range increases. Hence, the result follows from part (a) of

this proposition. Now consider the variance (σ^2):

$$\begin{aligned}\sigma^2 &\equiv \int_a^b (F - E[F])^2 dG(F) \\ &< (b - a)^2 \int_a^b dG(F) \\ &= b^2 + a^2 - 2ab < 2b^2\end{aligned}$$

where the last inequality uses the nonnegativity of a . The result then follows by the same argument as for the range.⁹

Part (a) of Proposition 5 asserts that, if there is some probability that the fixed cost will exceed the maximum net surplus that could be obtained from producing the good, then (nontrivial) Nash consumption equilibrium will be unique. The same is true by part (b) of Proposition 5 if uncertainty is such that g vanishes at its upper bound. Note that this can be true with arbitrarily little uncertainty; for example, consider an exponential distribution of F (but with a bounded away from zero for realism) with arbitrarily small variance. Part (c) of Proposition 5 shows that the same is true in a finite economy if there is enough uncertainty present.

The incentive to protect one's surplus continues to influence consumer choice in the uncertainty model. This incentive is present as long as the probability that the firm will produce is less than 1. This incentive confronts every consumer in an interior equilibrium, and every consumer engages in excessive consumption. Since increasing the probability that the firm produces is a public good, this result may seem surprising in light of the extant literature on provision of public goods in Nash contribution games (see Theodore Bergstrom et al. [1986] and the references therein). A result of this lit-

⁸If $(p - c)\sum \hat{q}_i(p) = b$, then $q_i^* = \hat{q}_i$ is the unique equilibrium.

⁹An alternative proof shows that $g(b)$ converges to zero as the variance grows (for a fixed mean) and then appeals to part (b) of Proposition 5. This is notable, since it does not require that $\sum CS_i(c, q_i^f)$ is finite, thus applying to a market with an infinite number of consumers.

erature is that free-riding is very likely (see James Andreoni, 1988; Timothy L. Fries et al., 1991). The relevant difference is that here the marginal cost to consumers of increasing their consumption beyond demand begins at zero. Hence, every consumer engages in excessive consumption. In contrast, the marginal cost of making a monetary contribution to a public good is 1, and only those individuals for whom the marginal benefit exceeds 1 will contribute positively.

In a corner equilibrium, it is possible that the excessive consumption by a subset of consumers resolves the problem of probabilistic provision for all consumers. Here, not all consumers will necessarily engage in excessive consumption in equilibrium. Motivated by Proposition 5, I consider further only the case in which an interior equilibrium arises.¹⁰ Hence, assume any one of the conditions of Proposition 5 prevails in all that follows.

There are two externalities of consumption in an interior equilibrium. First, one consumer's increased consumption benefits other consumers by increasing the probability that the firm produces. Second, the firm obviously benefits. These externalities prevent an interior equilibrium from being socially efficient. The next proposition formalizes this point. I adopt expected welfare

$$\begin{aligned}
 (7) \quad E[W] &= \Sigma E[CS_i] + E[\Pi] \\
 &= G[(p-c) \Sigma q_i] \Sigma CS_i(p, q_i) \\
 &\quad + \int_a^{(p-c)} \Sigma q_i [(p-c) \Sigma q_i - F] dG(F)
 \end{aligned}$$

as the social-welfare measure. In addition, I will use the fact that equilibrium price must exceed c , which is shown below.

PROPOSITION 6: *An interior equilibrium is never socially efficient.*

¹⁰A longer version of this paper (see footnote 1) examines further the properties of corner equilibria. Also, see Shmuel Nitzan and Romano (1990), who examine Nash contribution games for discrete public goods with uncertain costs.

PROOF:

In an interior equilibrium, $\partial E[CS_i]/\partial q_i = 0$. It is straightforward to check that $\partial E[CS_j]/\partial q_i > 0$ for all $j \neq i$; and, using that $p > c$, $\partial E[\Pi]/\partial q_i > 0$. Then, $E[W]$ can be increased by increasing q_i .

The force of the externalities worsens as the economy grows. The consequence of this is seen by examining the following replication. Let n increase and keep the fixed cost *per customer* constant. Correspondingly, reinterpret F as the fixed cost per customer and replace $G(F)$ with $G(F/n)$ in the above analysis. It is straightforward to confirm that the equilibrium probability of production approaches that without any excessive consumption as n increases. Hence, near free riding prevails in large economies, and the empirical relevance of this analysis is limited to cases with sufficiently small numbers.

The firm chooses price anticipating the outcome of the consumption stage. To analyze this, let $N(p) \equiv \Sigma q_i^*(p)$, which is unique under the assumptions. The firm's price choice maximizes its expected profits, which equal $\int_a^{(p-c)N(p)} [(p-c)N(p) - F] dG(F)$. This problem is equivalent to

$$(8) \quad \max_p (p-c)N(p)$$

or, also, maximization of the probability of ultimate production. The final proposition regards this maximization.

PROPOSITION 7: (a) *The firm will have positive expected profits in equilibrium.* (b) *The optimal price may be uniquely determined.*

PROOF:

(a) The firm produces only for realizations of F in which it earns nonnegative profit, and so the result follows from the fact that $G > 0$ at the optimum. (b) See the example in the following subsection.

In contrast to the certain case, the firm strictly prefers entering here. Price is not always uniquely determined, because $N(p)$

need not be well behaved.¹¹ It has proved futile to search for meaningful conditions that guarantee uniqueness of price. It is easy, however, to provide an example in which $N(p)$ is well behaved and price is unique.

C. An Example

Let cost be given by $C = q + F$, where F has a uniform distribution with support $[0, b]$. There are two identical consumers with demands $d_i = A - p$, $i = 1, 2$, where $A > 1$. It is easy to check that Assumptions 2 and 3 are satisfied. Since $p_m = (A + 1)/2$, $G[(p_m - c)\sum d_i(p_m)] = (A - 1)^2/2b$, and thus Assumption 1' requires that $b > (A - 1)^2/2$. The i th consumer's expected consumer surplus is given by

$$\begin{aligned} E[CS_i] &= \left[\int_0^{q_i} (A - x) dx - pq_i \right] \\ &\quad \times G[(p - 1)(q_i + q_j)] \\ &= (p - 1)(q_i + q_j) \\ &\quad \times [(A - p)q_i - q_i^2/2] / b \\ &\quad i = 1, 2, i \neq j \end{aligned}$$

where it is assumed that $G < 1$ (which conforms to an interior equilibrium). Maintaining the latter assumption for the moment, the Nash equilibrium values satisfy

$$\begin{aligned} (9) \quad &2(A - p)q_i - 3q_i^2/2 \\ &+ q_j(A - p - q_i) = 0 \\ &i = 1, 2, i \neq j. \end{aligned}$$

The unique solution to (9) is $q_i^* = q_j^* = 6(A - p)/5$, which implies $N(p) = 12(A - p)/5$. Then, the firm maximizes $(p - 1)N(p)$, with solution $p^* = (A + 1)/2$. All this assumes that $G[(p - c)N(p)]$ is less than 1 for all p . This requires $b > 3(A - 1)^2/5$.

III. Summary and Concluding Remarks

The economic setting in which average cost lies beyond demand is traditionally regarded as one in which the good will not be produced, although this may be suboptimal. I have shown that there is often a Nash equilibrium in consumption in which the good is produced in this setting. Individuals consume beyond their demands to keep the firm in business and to protect their surpluses. With perfect information, there are multiple equilibria; and the model fails to predict uniquely price and the consumption pattern. By introducing consumer uncertainty about cost, the multiple-equilibrium problem often disappears. Moreover, all that is required to generate excessive consumption is consumers' perception of some chance that the firm will exit without such behavior.

In the more realistic uncertain case, excessive consumption declines as the economy is replicated. This limits the empirical relevance of the model. The effect of excessive consumption is likely to be significant only in small local economies. Some examples of local monopolies resulting from large fixed costs relative to market size are ethnic and fast-food restaurants, speciality food and beverage stores, fresh-fish markets, professional stage theaters, and taxi and airline services. The presence of local monopoly does not itself provide evidence of excessive consumption. It is casual empiricism that motivated this study. I have, for example, observed the somewhat reluctant purchase of season tickets to the local theater despite the availability of tickets to every play. An empirical test for excessive consumption could be constructed as follows. The model with uncertainty about the fixed cost also predicts that an individual's consumption decreases in the number of consumers (without replication of fixed cost) once the market is small enough that there is a positive probability of exit.¹² The model then

¹¹A longer version of this paper (see footnote 1) contains an example in which $N(p)$ has an upward-sloping range.

¹²This can be shown using (4a) and Assumption 2. A proof is in a longer version of this paper (see footnote 1).

predicts a negative coefficient on sufficiently small market sizes in a regression that explains an individual's consumption.

Enough said, as I am on my way (again) to a mediocre Chinese restaurant, but the only one in town that serves a good Peking Duck.

APPENDIX

PROOF OF LEMMA 1:

Taking derivatives yields

$$(A1) \quad \frac{\partial E[CS_i]}{\partial q_i} = (d_i^{-1} - p)G + (p - c)gCS_i$$

$$= [d_i^{-1} - p + (p - c)CS_i g / G]G$$

and

$$(A2) \quad \frac{\partial^2 E[CS_i]}{\partial q_i^2} = [d_i^{-1} - p + (p - c)CS_i g / G]g + d_i^{-1} + (p - c) \left[(d_i^{-1} - p)g / G + CS_i \frac{\partial(g/G)}{\partial q_i} \right]$$

Strict quasi-concavity is implied if $E[CS_i]$ is strictly concave whenever $\partial E[CS_i] / \partial q_i$ vanishes, since then there exists no interior minimum. From (A1) and (A2), if $\partial E[CS_i] / \partial q_i = 0$, then the sign of $\partial^2 E[CS_i] / \partial q_i^2$ equals the sign of what follows the first term in (A2). Recalling that g/G is nonincreasing, the result then follows if $CS_i \geq 0$ and $d_i^{-1} - p \leq 0$. Now, $d_i^{-1} - p > 0$ implies $CS_i > 0$. If these hold, one can see by inspection that (A1) cannot vanish. The other possibility would have $d_i^{-1} - p \leq 0$ and $CS_i < 0$. Again (A1) could not vanish. Hence, the result follows.

PROOF OF LEMMA 2:

I show that there exists an equilibrium with $G > 0$ in an artificially restricted game and then show it to have properties implying that it is also an equilibrium in the game of interest. Let the Cartesian product of strategy sets in the restricted game be given by $S = \{q: (p - c)\sum q_i \geq a \text{ and, for all } i, 0 \leq$

FIGURE 4. A RESTRICTED GAME WITH TWO CONSUMERS

$q_i \leq \bar{q}_i$). Figure 4 illustrates a case of two consumers. The first restriction on the vector q is the "artificial one," (i.e., the game of interest drops this requirement). Since p satisfies Assumption 3 in the text, S has an interior. Also, S is closed and convex. Then, since the i th payoff function is continuous and quasi-concave in q_i (Lemma 1), the choice correspondence satisfies the hypotheses of Kakatani's fixed-point theorem; and hence there will exist an equilibrium in the restricted game. See James W. Friedman (1986 pp. 36-9) for details.

Now I show that no equilibrium in the restricted game can occur on the "south-westerly bound" of S where $(p - c)\sum q_i = a$ and G vanishes. Let $\bar{q} = (\bar{q}_1, \bar{q}_2, \dots, \bar{q}_n)$ denote a choice on this bound. Since G would vanish, $E[CS_i] = 0$ for all i . But, for any $q_i \in (\bar{q}_i, \bar{q}_i)$, $E[CS_i] > 0$, implying that \bar{q}_i cannot be a best response. Hence, equilibrium must occur elsewhere in S and, in particular, have $G > 0$. Any equilibrium in the restricted game must then also be an equilibrium in the unrestricted game. The unrestricted game adds only strategy space where $E[CS_i] = 0$, which will never contain a better response than a best response in S . Hence, there always exists an equilibrium in the unrestricted game with $G > 0$.

PROOF OF PROPOSITION 4:

(a) First I show that there exists an equilibrium with $0 < G < 1$. Since it is known

from Lemma 2 that there exists an equilibrium with $G > 0$, it suffices to show that there is no equilibrium with $G = 1$. Suppose that there is such an equilibrium. Then, since $(p - c)\Sigma \hat{q}_i < b$, $q_i^* > \hat{q}_i$ for some i . However, from Lemma 1 and equation (6), this implies that q_i^* cannot be a best response [(5a) would not be satisfied for i]. Hence, any equilibrium must have $0 < G < 1$ and satisfy (4a) and (4b).

To show the remaining results, rewrite (4a) as

$$(A3) \quad \frac{d_i^{-1}(q_i^*) - p}{(p - c)CS_i(p, q_i^*)} = - \frac{g[(p - c)Q^*]}{G[(p - c)Q^*]}$$

where $Q^* \equiv \Sigma q_i^*$. Since the right-hand side of (A3) is negative, it must be that $d_i^{-1} - p < 0$. This establishes that $q_i^* > d_i$ (i.e., every consumer engages in excessive consumption). Equation (A3) is of the form $\phi_i(q_i) = \psi(Q)$, where

$$\phi_i' = \frac{d_i^{-1}(p - c)CS_i - (d_i^{-1} - p)^2(p - c)}{(p - c)^2 CS_i^2} < 0$$

and $\psi' \geq 0$ since g/G is nonincreasing (recall Assumption 2). Therefore, $q_i = H_i(Q)$, where $H_i(Q) \equiv \phi_i^{-1}(\psi(Q))$. Then,

$$(A4) \quad Q^* = \Sigma H_i(Q^*).$$

Since $\phi_i' < 0$ and $\psi' \geq 0$, $H_i' \leq 0$ for each i , implying that (A4) can have no more than one solution. Thus, equilibrium is unique.

(b) I show first that there exists an equilibrium with $G = 1$ by using Lemma 2 and demonstrating that no equilibrium with $0 < G < 1$ exists. Since $(p - c)\Sigma \hat{q}_i(p) > b$, the latter such equilibrium would require that $q_i^* < \hat{q}_i$ for some i . From Lemma 1 and equation (6), then (4a) would not be satisfied (i.e., q_i^* could not be a best response).

To see the remaining results, note that using Assumption 1' yields

$$(p - c) \Sigma d_i(p) < b < (p - c) \Sigma \hat{q}_i(p).$$

It is clear then that there exist multiple vectors with the properties $q_i \in [d_i, \hat{q}_i]$ and $\Sigma q_i = b$, each of which must have $q_i > d_i$ for some i . Using (5a), (5b), (6), and Lemma 1, it is straightforward to check that each of these is an equilibrium vector, and it is clear that there can be no others. That $q_i > d_i$ for some i implies that at least one consumer engages in excessive consumption.

Capital Formation and Productivity Convergence Over the Long Term

By EDWARD N. WOLFF*

Catch-up in total factor productivity (TFP) among the "group of seven" was evident between 1870 and 1979, though much slower before 1938 than after 1950. Capital:labor ratios also converged over the long period, though the process was much stronger after 1960. TFP catch-up is found to be positively associated with capital:labor growth and strongest when capital intensity is growing most rapidly. The United States overtook the United Kingdom in technological leadership in 1900 when its capital:labor growth was more than three times higher. The steady deterioration in the United Kingdom's relative TFP since 1900 and the United States' since 1950 are both associated with low rates of capital formation. (JEL O57, O30, J24, O40)

Recent studies have documented a convergence both in average labor productivity levels and in per capita income over the last century or so and particularly since the end of World War II among industrialized economies (see e.g., Moses Abramovitz [1979, 1986], Angus Maddison [1982, 1987], Gottfried Bombach [1985], and William Baumol [1986] for labor productivity statistics; Baumol and Wolff [1988] for GDP per capita; and Steve Dowrick and Duc-Tho Nguyen [1989] for total factor productivity). Abramovitz's (1986) and Baumol's (1986) results, in particular, highlight these trends. They found an almost perfect inverse relation between labor productivity levels in 1870 and the rate of labor productivity growth between 1870 and 1979 among 16 Organization for Economic Cooperation and Development (OECD) countries. In addition, the coefficient of variation in productivity levels, defined as the ratio of the standard deviation to mean productivity, fell from 0.48 in 1870 to 0.16 in 1979.

Abramovitz (1986) also investigated sub-periods and found that labor productivity convergence was much slower in the period before World War II than after. Indeed, even in the postwar period, there is evidence from Abramovitz and from Baumol and Wolff (1988) that productivity convergence has slowed down during the 1970's, though this is disputed by Dowrick and Nguyen, who find parameter stability in their catch-up model between pre- and post-1973 periods when controlling for factor-intensity growth. Abramovitz also found that there were significant changes in leadership and the rank order of countries over time. Results of Bradford De Long (1988) show very little evidence of productivity convergence over the last century when the sample is no longer restricted to OECD countries. However, Baumol and Wolff, using the Robert Summers and Alan Heston (1988) sample, which covers countries at all levels of development, found convergence in real GDP per capita among the top third or so over the 1950-1981 period, though it was weaker than among OECD countries alone.

Explanations of the productivity catch-up almost all involve the so-called "advantages of backwardness," by which it is meant that much of the catch-up can be explained by the diffusion of technical knowledge from the leading economies to the more backward ones (see e.g., Alexander

*Department of Economics, New York University, New York, NY 10003. I thank the National Science Foundation, the Exxon Foundation, and the C. V. Starr Center for Applied Economics for support of the research. I also thank William Baumol, Moses Abramovitz, and four anonymous referees for their valuable suggestions.

Gerschenkron, 1952; Simon Kuznets, 1973). Indeed, the further an economy is from the technological frontier, the greater the rate of technical advance possible from such borrowing. However, being backward does not itself guarantee that a nation will catch up. Other factors must be present, such as strong investment (see Abramovitz [1979 p. 2] for a discussion of potential advances in productivity from capital accumulation), an educated work force, a suitable product mix, and developed trading relations with advanced countries. This paper investigates the role of capital formation in the process of productivity catch-up.

This study considers three hypotheses (which are not mutually exclusive) to account for the observed convergence in labor productivity levels among the advanced nations. The first is the "catch-up" hypothesis, which states that countries that lag furthest behind the leading countries in terms of technology level should exhibit the most rapid rate of growth in technology. This would also imply convergence in total factor productivity (TFP) levels, defined as the ratio of output to a weighed sum of labor and capital inputs, among nations. The second hypothesis is that the convergence in labor productivity levels has been due to narrowing of differences in factor intensities (capital:labor ratios) among industrialized countries.

The third hypothesis is that there are positive interactions between capital accumulation and technological advance. This deserves some comment. There are several avenues through which capital formation and total factor productivity growth may be associated. First, it is likely that substantial capital accumulation is necessary to put new inventions into practice and to effect their widespread employment. This association is often referred to as the "embodiment effect," since it implies that at least some technological innovation is embodied in capital. It is also consistent with the "vintage effect," which states that new capital is more productive than old capital per (constant) dollar of expenditure. If the capital stock data do not correct for vintage effects, then a positive correlation should be observed

between the rate of technological gain and the change in the growth rate of capital.

A second avenue is that the introduction of new capital may lead to better organization, management, and the like. This may be true even if no new technology is incorporated in the capital equipment. A third avenue is through learning-by-doing (see Kenneth Arrow, 1962). Thus, technological advance should be correlated with the accumulation of capital stock. Fourth, potential technological advance may stimulate capital formation, because the opportunity to modernize equipment promises a high rate of return to investment. A fifth avenue is through the so-called Verdoorn or Kaldor effect, whereby investment growth may lead to a growth in demand and thereby to the maintenance of a generally favorable economic climate for investment. Such positive feedbacks may act cumulatively. These last four arguments do not lead to a specific functional relation between TFP growth and the rate of capital or capital:labor growth but do suggest a positive correlation between the two sets of variables.

In my analysis, it is not possible to distinguish among these various effects, and I will refer to them collectively as interaction effects or complementarities between capital accumulation and technological advance. Moreover, as is apparent, it is not possible to attribute causation one way or the other, since the influence between TFP growth and capital formation runs in both directions. However, it is possible to test for these interaction effects, and results will be reported below.¹

The empirical analysis is limited to the "group of seven"—Canada, France, Germany, Italy, Japan, the United Kingdom, and the United States—over the 1870–1979 period, because of the availability of consistent data on total capital stock for this period provided in Maddison (1982). This sample is by no means representative and is

¹Also, see Richard Nelson (1964), Kuznets (1973), Abramovitz and Paul David (1973), Bombach (1985), and Robert Solow (1988) for related discussions.

subject to many of the same criticisms made by De Long (1988) of the OECD samples.

Support is found for the three hypotheses. First, TFP levels converged among the group of seven over the 1870–1979 period. However, the pattern is far from uniform, with convergence much stronger after World War II than before, as Abramovitz (1986) found for labor productivity. Second, aggregate capital:labor ratios showed convergence over the long period, though the process was much stronger after 1960; before World War II, it is evident only when the United States, which surged ahead of the other countries between 1900 and 1938, is excluded from the sample. Technological advance and capital formation played about equal roles in labor productivity growth.

Third, the data show a positive correlation of 0.79 between the rate of TFP growth and that of the capital:labor ratio over the 1880–1979 period. Results, based on regression analysis and a vintage model, are somewhat mixed but generally support the existence of an interaction effect between technological advance and capital accumulation. The effect was strongest during the postwar period, when both capital:labor growth and the speed of technological catch-up were greatest. Overall, convergence in labor productivity levels is found to be a consequence of all three effects.

The next part of the paper provides evidence of convergence in productivity levels, and Section II presents statistics on growth in capital and changes in capital intensity over time. Section III considers the relation between capital formation and the rate of technological progress. Concluding remarks are made in the last section.

I. Productivity Catch-Up

The TFP level for country h is defined as the ratio of total output (Y^h) to a weighted average of labor input (L^h) and capital input (K^h)

$$(1) \quad TFP^h = Y^h / [\alpha^h L^h + (1 - \alpha^h) K^h]$$

where the labor input is measured by hours of work, the capital stock is measured by

gross nonresidential fixed plant and equipment, and α^h is the wage share in country h .² Total factor productivity growth is based on the Divisia measure, ρ , defined as

$$(2) \quad \rho^h = \hat{Y}^h - \alpha^h \hat{L}^h - (1 - \alpha^h) \hat{K}^h$$

where a superscript “hat” ($\hat{}$) indicates the relative rate of change (see Frank Gollup and Dale Jorgensen [1980] for a discussion of the Divisia index). The Tornqvist approximation based on average period shares is employed.³

The choice of the proper factor shares is debatable. Under the assumption that technology is the same across countries and that factor prices are equalized, as in the Heckscher-Ohlin model (see e.g., Edward Leamer, 1984) factor shares should be equal among countries, so that international average factor shares provide the best approximation. On the other hand, if technology differs among countries, then country-specific wage shares should be used. The results point to the latter choice. However, the only available data for the full 1870–1979 period are employee compensation (EC) and national income (NI) for the United Kingdom and the United States, so that factor shares are based on the average ratio of EC to NI in the two countries.⁴

²John Kendrick and R. Sato (1963) demonstrate that this index can be derived as a special case of the CES production function.

³Two other indexes were employed. First, the translog index of TFP level [see equation (4) in Section III] was used as an alternative to equation (1). Second, the time derivative of equation (1) was used as an alternative to the Divisia index. Results are similar to those based on (1) and (2) and are not reported here.

⁴For the postwar period, data availability is much greater, and therefore several alternative measures of factor shares were constructed, including the ratio of EC to GDP, the inclusion of a labor portion of entrepreneurial (self-employment income) in the wage share, and country-specific factor shares. In addition, net capital stock estimates were also available for all countries except Italy. Furthermore, since, productivity movements are sensitive to business-cycle fluctuations, the TFP index was also adjusted for capacity utilization, as

$$(1') \quad TFPU^h = Y^h / [\alpha^h L^h + (1 - \alpha^h) u^h K^h]$$

TABLE 1—TOTAL FACTOR PRODUCTIVITY (TFP) LEVELS, 1870–1979

^aTFP levels are computed according to equation (1). Output is measured by GDP, labor by hours worked, and capital by gross nonresidential fixed plant and equipment (net for Germany). Factor shares are based on the average ratio of employee compensation to national income for the United Kingdom and the United States over the 1870–1979 period.

^bCoefficient of variation, defined as the ratio of the standard deviation to the mean.

^cRatio of the maximum to the minimum productivity level.

^dRatio of unweighted average productivity level of all countries except the United States to U.S. productivity level.

Table 1 shows computations of TFP levels for the period from 1870 to 1979.⁵ It should be noted that the sample of countries diminishes as one goes further back in time because of data availability. The United

Kingdom was the early leader in total factor productivity. The United States caught up to the United Kingdom by 1890 and led

where u is the capacity utilization rate, based on the utilization index for the manufacturing sector. Results did not materially differ from those reported here and are not shown.

⁵The primary data source on output, gross capital stock, and hours worked is Maddison (1982), in which

problems of comparability of measures across countries are discussed. Estimates of GDP and man-hours for the 19th century are based on partial data. Many of the estimates are performed through backward interpolation of average growth rates. This has the effect of smoothing out the series and biasing the results toward convergence. Random errors of measurement at period end points will also likely bias the results in favor of convergence (see Abramovitz [1986] for a discussion of

thereafter. The United Kingdom remained in second place until 1950, when it was overtaken by Canada; by 1979, it had fallen to fifth (out of seven countries). Japan was last throughout the period, though its TFP relative to the United States increased from one-fourth in 1880 to three-fourths in 1979.

this point). Input measures do not adequately capture differences in natural resources, particularly land. This is particularly problematic for the early years (1870–1913), when the economies of these countries had a large agricultural sector. Because of the land:labor-ratio advantage of the United States and the declining share of agriculture in GDP over time of all seven countries, the technological gains of the United States relative to other countries will be understated by the TFP estimates. Differences in human capital are not reflected in the data. Differences in service-life assumptions, retirement patterns, depreciation schedules, and capital prices among countries will lead to inconsistencies in capital stock estimates among countries. Maddison attempted to standardize the estimates by benchmarking each national capital stock series to specially constructed 1976 estimates for each country, using international capital prices and the same assumptions with regard to service life and retirement patterns. Remaining errors in measurement will have the effect of overstating the variance of capital:labor ratios across countries and understating the variation of TFP relative to labor productivity. Also, see Abramovitz (1986) for further discussion of weaknesses in the long-term data.

Other data sources are as follows. Estimates of net capital stock are derived from Raymond Goldsmith (1985). The 1950 figures are from table 18 of Goldsmith; estimates for other years are based on individual country tables and geometric interpolation. Data on utilization rates are from the OECD's *Main Economic Indicators, 1960–1979* and David Coe and Gerald Holtham (1983). Data on wage shares are computed from the following sources: (i) data for 1950–1979 are from the United Nations' *Yearbook of National Accounts Statistics*, selected years, except for the 1950–1960 period in Italy; (ii) data for 1937–1950 and for 1950–1960 in Italy are from the International Labour Organization's *Yearbook of Labor Statistics*, various years; (iii) for Japan, data for 1920–1937 are from Kasushi Ohkawa and Henry Rosovsky (1973 pp. 316–7); (iv) for the United Kingdom, data for 1870–1938 are from Phyllis Deane and W. A. Cole (1964 p. 247); (v) for the United States, data for 1870–1938 are from D. Gale Johnson (1954); (vi) data on entrepreneurial income are from the United Nations' *Yearbook of National Accounts Statistics*, various years. The apportionment of entrepreneurial income into a wage and profit component is based on Johnson (1954), who estimated a 65-percent share for labor compensation and a 35-percent share for return on capital.

According to three indexes (the ratio of maximum to minimum TFP levels, the coefficient of variation, and the average TFP level of the other countries relative to the United States), there was only moderate convergence between 1880 and 1929 (particularly between 1880 and 1913). This is similar to labor productivity movements among the five countries.⁶ The Depression years did bring some convergence in TFP levels, followed by a sharp increase in dispersion between 1938 and 1950. This was partly a consequence of the deleterious effect of World War II on German and Japanese productivity, which declined in absolute terms, but mainly due to a tremendous increase in U.S. productivity. Another indicator of catch-up is a negative correlation of TFP growth rates with initial TFP levels. These coefficients show the same pattern: -0.20 for 1880–1913, -0.33 for 1880–1929, -0.64 for 1880–1938, and -0.83 for 1880–1979.

The postwar period (1950–1979 here) provides a relatively good case study of the catch-up process, because it is the longest stretch of time unbroken by a major war or a depression. Over this period, the coefficient of variation fell by more than two-thirds, the ratio of maximum to minimum TFP level declined by about two-thirds, and average TFP relative to the United States rose from 0.54 to 0.85. Moreover, the correlation of TFP growth rates with initial TFP levels (in 1950) was -0.96 .⁷

Results are also shown for average annual rates of both TFP and labor productivity growth. TFP growth averaged 1.4 percent per year over the 1880–1979 period,

⁶However, the results differ from Abramovitz's (1986) finding for labor productivity trends among 16 OECD countries. In particular, the coefficient of variation in labor productivity levels decreased from 0.51 in 1870 to 0.48 in 1880, 0.33 in 1913, and 0.29 in 1929. Thus, slow declines were observed for 1870–1880 and 1913–1929.

⁷Correlations were equally strong using the alternative measures of TFP introduced in footnote 4. Computations of correlation coefficients that exclude Japan were quite similar in magnitude. Correlations between TFP growth and the natural logarithm of initial TFP were even stronger.

and labor productivity growth averaged 2.5 percent per year. Japan led in both, while the United Kingdom was last. The ratio of TFP to labor productivity growth, a rough measure of the contribution of technical change to labor productivity growth, averaged 0.57, with the remaining portion due to capital deepening. There was relatively little variation among the five countries in the sample.

Over the 1880–1938 period, there were greater differences among countries. A comparison of the United Kingdom and the United States is revealing. Both experienced the same TFP growth. However, labor productivity growth was substantially lower in the United Kingdom, because of a much smaller growth in capital intensity. In fact, only a third of the United Kingdom's labor productivity growth was attributable to capital-deepening, in comparison to 60 percent for the United States. Over the postwar period, the ratio of TFP to labor productivity growth averaged 0.59, compared to 0.51 during 1880–1938, and there was less variation among countries.⁸

In sum, the period before World War II was one of moderate growth in both TFP and labor productivity and moderate catch-up in TFP levels. In contrast, the postwar period was characterized by strong growth in productivity and rapid convergence in productivity levels.

II. Capital Intensity

There are two apparently conflicting sets of results with regard to convergence in aggregate capital:labor ratios. According to the three summary measures shown in Table 2, there was slightly increasing disparity in capital:labor ratios before World War II and rapid convergence after 1960.⁹ How-

ever, correlations between initial capital:labor ratio and its rate of growth show catch-up in capital intensity: -0.28 for 1880–1913, -0.59 for 1913–1938, 0.24 for 1938–1950 and -0.91 for 1950–1979. For the full 1880–1979 period, the correlation was -0.97 . Thus, except for the period covering World War II, countries with lower initial levels of capital intensity experienced faster growth in their capital:labor ratio. The discrepancy is due to the very rapid growth in U.S. capital intensity between 1890 and 1938, by which time its capital:labor ratio was three times the average of the others. Indeed, when the United States is eliminated from the sample, the coefficient of variation in capital intensity shows a decline from 0.68 in 1880 to 0.37 in 1938.

The United Kingdom was the most capital-intensive in 1870 and 1880. The United States led in capital:labor growth during the 1880–1913 period and by 1890 was the most capital-intensive country, a position it held through 1970 (by 1979, Germany had become the most capital-intensive). U.S. capital-intensity growth was more than three times greater than the United Kingdom's between 1880 and 1913, which explains the emergence of the United States as the leader in labor productivity.

Three important relations become apparent from the data. First, there is a direct correspondence by period between the degree of capital-intensity catch-up and TFP convergence: strongest in 1950–1979, second strongest in 1913–1938, weakest in 1880–1913, and divergent in 1938–1950. Second, there is also a direct correspondence by period between TFP convergence and the average growth in capital intensity: highest in 1950–1979 (average capital:labor growth of 4.4 percent per year), next in 1913–1938 (2.2 percent), third in 1880–1913 (1.9 percent), and last in 1938–1950 (1.2 percent).¹⁰ Third, countries with higher cap-

⁸Maddison (1987) computed a higher average ratio of 0.74 over the 1950–1973 period for six countries: France, Germany, Japan, the Netherlands, the United Kingdom, and the United States. The difference is mainly due to Maddison's higher labor shares.

⁹Results for the postwar period are quite similar for the ratio of net capital stock to hours of work.

¹⁰A regression of the coefficient of variation of TFP levels on the average capital:labor growth rate for each of ten periods yields a highly significant negative coefficient on capital:labor growth.

TABLE 2—CAPITAL:LABOR RATIOS, 1870–1979

Country	Ratio of gross capital to hours (index numbers, standardized so that GDP per hour = 1.00 for United States in 1950) ^a

^aThe labor input is measured by hours worked and capital by gross nonresidential fixed plant and equipment (net for Germany). Calculations of the mean, standard deviation, and coefficient of variation are based on countries in the sample with the relevant data.

^bCoefficient of variation, defined as the ratio of the standard deviation to the mean.

^cRatio of unweighted average for all countries except the United States to the U.S. value.

ital:labor growth generally had higher TFP growth. The rank order is identical for the postwar period: Japan (annual capital:labor growth of 7.1 percent), Germany (5.7 percent), Italy (5.1 percent), France (4.2 percent), United Kingdom (3.6 percent), Canada (3.0 percent), and the United States (2.4 percent). For the whole 1880–1979 period, Japan was first in capital:labor growth, followed by Italy, Germany, the United States, and the United Kingdom. Except for a reversal between Italy and Germany, the rank order was identical to that of TFP

growth. These empirical findings suggest the existence of interaction effects between capital growth and technology growth.

III. Interactions Between Capital Accumulation and Productivity Growth

I use a standard growth-accounting framework to assess the extent to which convergence in technology levels is associated with capital accumulation through interaction effects between the two. Formally, assume that for each country h there

is a Cobb-Douglas value-added production function:

$$(3) \ln Y^h = \zeta^h + \alpha \ln L^h + (1 - \alpha) \ln K^h.$$

The parameter ζ^h is country-specific and indicates country h 's technology level. The output elasticity of labor, α , is assumed to be the same across countries. If factors are paid their marginal products, then the output elasticity is equal to labor's distributional share. This study will use the cross-country (unweighted) average of labor's share as the estimate of α .

Next, define the translog index of TFP level:

$$(4) \ln TFP^h = \ln Y^h - \alpha \ln L^h - (1 - \alpha) \ln K^h$$

which is consistent with the Divisia index of TFP growth. Comparison of equation (4) with equation (3) reveals that this measure of TFP level is implicitly based on a Cobb-Douglas form for the production function. Moreover, let the United States be the benchmark country, and define the following:

π^h : ratio of country h 's labor productivity to U.S. labor productivity;

τ^h : ratio of country h 's technology level to U.S. technology level;

κ^h : ratio of country h 's capital:labor ratio to U.S. capital:labor ratio.

Equations (3) and (4) then imply that

$$(5) \ln \pi^h = \ln \tau^h + (1 - \alpha) \ln \kappa^h.$$

Differentiating this with respect to time yields

$$(6) \hat{\pi}^h = \hat{\tau}^h + (1 - \alpha) \hat{\kappa}^h.$$

Capital formation may be expected to exert two distinct effects on labor productivity. First, by raising the capital:labor ratio, it will increase labor productivity even if there is no advance in technology in use [equation (6)]. Second, through interactions with technology advance, accumulation may be associated with gains in productivity over and

above capital deepening. Three approaches for testing the interaction effect are considered here.

A. Correlation Between TFP and Capital:Labor Growth

The first and most direct test is to determine whether there is a positive correlation between $\hat{\tau}$ and $\hat{\kappa}$. Though this approach is not consistent with a strict vintage model, it probably captures the general set of interactions between the two variables, as discussed in the introduction. The correlation coefficient was 0.08 for 1880–1913, 0.37 for 1913–1938, 0.55 for 1938–1950, 0.95 for 1950–1979 and 0.79 for the whole 1880–1979 period.¹¹ These results are generally consistent with the hypothesis that high rates of technical advance are associated with high rates of capital formation. However, they indicate that the relation was considerably stronger after World War II than during the prewar years.

B. Regression Analysis

A second approach uses a regression framework. Two basic specifications are employed:

$$(7a) \hat{\tau}_t^h = b_0 + b_1 \tau_t^h + b_2 \hat{\kappa}_t^h + \varepsilon_t^h$$

$$(7b) \hat{\tau}_t^h = b_0 + b_1 \tau_t^h + b_2 \Delta \hat{\kappa}_t^h + \varepsilon_t^h$$

where τ_t^h is country h 's (translog) TFP relative to the United States at the start of each period, $\Delta \hat{\kappa}_t^h \equiv \hat{\kappa}_t^h - \hat{\kappa}_{t-1}^h$, and ε is a stochastic error term. In some specifications, country dummy variables (except the United Kingdom) are included to control for country-specific effects, such as the degree of trade openness, culture, and government policy. In some, period dummy variables are also included to allow TFP growth to vary by period (e.g., in response to unevenness in the flow of new technology or inventions).

¹¹Other periods were used in the analysis, including 1880–1900, 1900–1913, 1900–1929, 1913–1929, 1929–1938, and 1929–1950, with similar results.

Notes: Numbers in parentheses below the coefficient estimates are *t* statistics. Key: τ^h = ratio of country *h*'s technology level to U.S. technology level; κ^h = ratio of country *h*'s capital:labor ratio to the U.S. capital:labor ratio. Computations are based on gross capital stock (net for Germany) and national income-based factor shares averaged between the United Kingdom and the United States. For regressions 1, 2, 4, and 6, observations are for Germany, Italy, Japan, and the United Kingdom for nine periods: 1880–1890, 1890–1900, 1900–1913, 1913–1929, 1929–1938, 1938–1950, 1950–1960, 1960–1970, and 1970–1979; Canada for 1929–1938, 1938–1950, 1950–1960, 1960–1970, and 1970–1979; and France for 1950–1960, 1960–1970, and 1970–1979; for regressions 3, 5, and 7, the 1880–1890 observation is excluded.

^aDurbin-Watson statistic, based on observations ordered within country over time.

*Significant at the 5-percent level; **significant at the 1-percent level.

The sample for (7a) consists of six countries (excluding the United States) for each of nine time periods (with available data): 1880–1890, 1890–1900, 1900–1913, 1913–1929, 1929–1938, 1938–1950, 1950–1960, 1960–1970, and 1970–1979; the sample size is 44. The sample for (7b) is the same, except that the 1880–1890 observation is excluded; the sample size is 38.

Two tests are made of the interaction hypothesis. The first [specification (7a)] posits a positive association between the rate of growth of relative productivity, $\hat{\tau}^h$, and the rate of growth of the relative capital:labor ratio, $\hat{\kappa}^h$. This is consistent with the general formulation of the interaction effect. The second [specification (7b)] posits a positive relation between $\hat{\tau}_i^h$ and the change in $\hat{\kappa}^h$. The latter is consistent with the strict vintage model, since the change in

the average age of the capital stock depends on the *acceleration* in the rate of capital growth (see Nelson, 1964). Also, as is implicit in the two specifications, the catch-up hypothesis is tested (a negative coefficient on τ^h).

Results for the interaction hypothesis, shown in Table 3, are generally supportive. Coefficient estimates for relative capital:labor growth are all positive (columns 2, 4, and 6). The coefficient estimate for $\hat{\kappa}$ is not significant when no country or period dummy variables are included, significant at the 5-percent level when country dummies are included, and significant at the 1-percent level when both sets are included. The latter is perhaps the most revealing result, since it suggests that it is the residual variation in TFP growth, after country- and time-specific effects are removed, that is

most strongly correlated with the variation in capital:labor growth.

The results for $\Delta \hat{\kappa}_t^h$ (columns 3, 5, and 7) are all positive, as predicted, but insignificant except when both country and time dummy variables are added, in which case it is statistically significant at the 5-percent level. Thus, (7a) provides a better fit to the data.¹² The results also confirm the catch-up hypothesis, at the 1-percent significance level, for this (highly selective) sample of countries.

The F test for the inclusion of the country dummy variables suggests that there are country-specific effects—economic, cultural, and institutional—that play an important role in productivity growth. Dummy variables (relative to the United Kingdom) are not significant for Canada and France in equation (7a) but are statistically significant at the 1-percent level and negative for Germany, Italy, and Japan. In other words, once relative backwardness and the rate of capital:labor growth are accounted for, Germany, Italy, and Japan had lower TFP growth than the United Kingdom. My results also held for the postwar period and differ from those of Dowrick and Nguyen, who found higher than predicted TFP growth for France, Germany, and Japan during 1950–1985, once these two factors were controlled. The reason for the difference in results is not readily apparent, though Dowrick and Nguyen use a different sample of countries and base their estimate of capital stock on investment flow data.

Moreover, the F test for the inclusion of period dummy variables is significant at the 1-percent level for each specification with country dummy variables. The only two period dummies that are statistically significantly different at the 5-percent level from 1970–1979 are 1929–1938, which is positive

(a consequence of low investment rates during the Depression), and 1938–1950, which is negative (from the effects of World War II on output).

Finally, when the regressions are performed separately for prewar data (1880–1938) and postwar data (1950–1979), results are much stronger for the latter. In particular, for equation (7a), with country dummy variables, the coefficient of $\hat{\kappa}$ is 0.306, which is significant at the 1-percent level, and the R^2 statistic is 0.95 for the 1950–1979 data.¹³ For the 1880–1938 data; the coefficient of $\hat{\kappa}$ is 0.088, which is not statistically significant, and the R^2 -statistic is 0.46. An F test (or “Chow test” from Gregory Chow [1960]) on structural change between the 1880–1938 data and the 1950–1979 data is statistically significant at the 1-percent level. The results are consistent with the correlation coefficients between TFP growth and capital:labor growth by period. I will have more to say about this in the conclusion.¹⁴

¹³One might assume at first glance that the postwar results are dominated by the German and Japanese reconstruction. However, when two interactive terms, $\hat{\kappa} \times \text{DUMGER}$ and $\hat{\kappa} \times \text{DUMJAP}$, are included in the specification, $\hat{\kappa}$ remains significant at the 1-percent level.

¹⁴Additional tests were performed for both the full sample and the postwar sample. First, the observations were ordered by time within each country in order to test for autocorrelation. The Durbin-Watson statistics, shown in Table 3, all fall within the critical range (5-percent level), except one in the uncertainty range. Second, standard heteroscedasticity tests were performed for each regression equation for τ_t^h and $\hat{\kappa}_t^h$ or κ_t^h , where appropriate. The test results are all insignificant at the 5-percent level. Third, Ramsey RESET functional-form tests were performed for the square and cube of the predicted value of the dependent variable, with no significant results at the 5-percent level. For column 6 of Table 3, the $F_{[2, 39]}$ statistic is 2.65, compared to a critical value of 3.23 at the 5-percent level. Fourth, an endogeneity test was performed for $\hat{\kappa}_t^h$ or κ_t^h , where appropriate, by first regressing $\hat{\kappa}_t^h$ on initial TFP and initial capital:labor ratio or κ_t^h on initial TFP and capital:labor growth, and then including the residual from this equation in the estimating equation. For column 6 of Table 3, the t statistic for the estimated residual is 1.1 and for column 7 the t statistic is 0.9. Two other specifications were also used:

$$(7c) \quad \hat{\rho}_t^h = b_0 + b_1 \tau_t^h + b_2 \hat{\kappa}_t^h + \varepsilon_t^h$$

$$(7d) \quad \hat{\rho}_t^h = b_0 + b_1 \tau_t^h + b_2 \Delta \hat{\kappa}_t^h + \varepsilon_t^h$$

¹²The variable $\hat{\gamma}_t^h \equiv \hat{K}_t^h - \hat{K}_t^{\text{US}}$ is also used in place of $\hat{\kappa}_t^h$ in (7a) and $\Delta \hat{\gamma}_t^h$ in place of $\Delta \hat{\kappa}_t^h$ in (7b). The former is insignificant except when both country and time dummy variables are added, in which case it is statistically significant at the 5-percent level. The latter is not statistically significant in any form. The interaction effect is more strongly related to changes in capital intensity than to changes in total capital stock.

C. Vintage Capital

A third approach is to construct a vintage model of productivity growth, which relates the level of productivity not only to the level of the capital stock but also to the age distribution of the capital stock. To simplify, suppose that this year's capital investment is s percent more productive than last year's and that the parameter s is constant over time. Let \bar{A}^h be the average age of country h 's capital stock. Then,

$$(8) \quad \ln Y^h = \zeta^h + \alpha \ln L^h + (1 - \alpha) \ln K^h - (1 - \alpha) s^h \bar{A}^h.$$

The average age of the capital stock is estimated from capital-stock data for 1870, 1880, 1890, 1900, 1913, 1929, 1938, 1950, 1960, 1970, and 1979. It is assumed that the service life is 50 years and that the average age of the capital stock was 25 years in 1870. Estimates are not provided for Canada or France, because the capital-stock series are not long enough.

Results on average age are shown in Table 4. Capital-stock age moves inversely with changes in the rate of growth of the capital stock. If growth accelerates, the average age of the capital stock declines. Changes in the rate of growth of the capital stock are positively associated with the actual rates of growth of the capital stock (the correlation coefficient is 0.60). The average age for the five countries declined from 23 years in 1880 to 21 years in 1913, rose steadily to 28 years in 1950, then rapidly declined to 15 years in 1979. It is also interesting that the standard deviation of capital-stock age increased between 1880 and 1938. Over the postwar period, it remained relatively constant, except for a drop in 1960. This is true despite the convergence in capital:labor ratios after 1960.

The United States had by far the newest capital stock from 1880 to 1913 (one-third

younger than the other four countries in 1900), a consequence of its high rate of capital growth. U.S. capital stock aged relative to the other countries from 1900 onward, and by 1979 it was 13-percent older than the that of other countries. From 1929 onward, Japan had the youngest capital stock; in 1979, its average age was two-thirds that of its nearest rival, Germany, and 0.58 that of the United States. In contrast, the United Kingdom had the oldest capital stock, a position it maintained for 100 years. In fact, in 1900, the U.K. capital stock was 70-percent older than that of the United States.

From (6) and (8) and with the added assumption that s is equal across countries, it follows that

$$(9) \quad \hat{\pi}^h = \hat{\tau}^h + (1 - \alpha) \kappa^h - (1 - \alpha) s \Lambda^h$$

where $\Lambda^h \equiv d\bar{A}^h/dt - d\bar{A}^{US}/dt$, the difference in the *rate of change* in capital-stock age between country h and the United States (see Nelson, 1964). I also estimated the following regression equation:

$$(10) \quad \hat{\tau}_t^h = b_0 + b_1 \tau_t^h + b_2 \Lambda_t^h + \varepsilon_t^h.$$

The results for Λ^h are all negative, as predicted, and significant at the 1-percent level when no dummy variables are included ($R^2 = 0.41$) and when country dummy variables are included ($R^2 = 0.55$). The estimated value of s , on the basis of the first two forms, is 0.0082.¹⁵

D. Capital:Output Constancy

A constant capital:output ratio within countries can also lead to a positive interaction effect between TFP growth and the growth in the capital:labor ratio. It follows from this that the correlation between country TFP growth (ρ^h) and the growth in

These differ from (7a) and (7b) in using actual country TFP and capital:labor growth rates instead of relative rates. The sample also includes data from the United States. Results are similar to those reported in Table 3.

¹⁵The variable Λ^h is significant at only the 10-percent level when both country and time dummy variables are added, as a result of the high multicollinearity of Λ^h with time. A simple regression of Λ^h on the eight time dummy variables yields an R^2 of 0.58.

TABLE 4—AVERAGE AGE OF CAPITAL STOCK AND CAPITAL:OUTPUT RATIOS, 1870–1979

^aAverage age is estimated from capital-stock data for 1870, 1880, 1890, 1900, 1913, 1929, 1938, 1950, 1960, 1970, and 1979. It is assumed that the service life is 50 years and that the average age of the capital stock was 25 years in 1870.

^bRatio of unweighted average ages for all countries except the United States to the U.S. age.

^cThe mean is the unweighted average for Germany, Italy, Japan, the United Kingdom, and the United States; the standard deviation is based on the same five countries.

the country capital:labor ratio ($\hat{k}^h \equiv \hat{K}^h - \hat{L}^h$) will be 1.0, even if technical change is disembodied. The result follows directly from (2) that, if $\hat{Y} = \hat{K}$, then

$$(11) \quad \rho_t^h = \alpha \hat{k}_t^h$$

or, equivalently,

$$(12) \quad \hat{\tau}_t^h = \alpha \kappa_t^h.$$

There are several theoretical justifications for this position. For example, in a Solow growth model, with a Cobb-Douglas production function with disembodied technical change such as (3), then in steady-state equilibrium the capital:output ratio will be constant (see Solow, 1956).

There are three testable implications of this model. First, capital:output ratios

should be constant over time. However, results in panels B and C of Table 4 indicate that country capital:output ratios have changed over long periods, such as for Italy and the United States for 1880–1938; Canada, France, and the United Kingdom for the 1950–1979 period; and Italy and Japan over the 1880–1979 period. On average, capital:output ratios trended upward between 1880 and 1979. Moreover, the standard deviation of capital:output growth rates does indicate noticeable differences in the experiences of the five countries. However, changes in capital:output ratios have been considerably less than those for capital:labor ratios.¹⁶

Second, the correlation coefficient between TFP growth and the growth in the capital:labor ratios should be unity. The cross-country correlation coefficients were 0.08 for 1880–1913, 0.37 for 1913–1938, 0.56 for 1938–1950, 0.95 for 1950–1979, and 0.79 for 1880–1979. Thus, except for the postwar period, the correlation coefficients are much lower than this model would predict.

Third, from (12), the regression coefficient of $\hat{\kappa}$ in equation (7a) should equal the mean wage share, which for this sample was 0.598. I performed t tests for $\hat{b}_2 = 0.598$ on the basis of the three sets of regression results reported in Table 3 for the 1880–1979 period, and the nulls were rejected at the 1-percent level (one-tail test) in two cases and at the 5-percent level (one-tail test) in the third case. It was also rejected at the 1-percent level for the regression on postwar data with country dummy variables. These results suggest that the finding of a positive interaction effect cannot be simply ascribed to capital:output constancy.

E. Increasing Returns to Capital

Paul Romer (1986) has argued that increasing returns to capital and externalities

from new knowledge development may account for rising worldwide productivity growth. This argument is based on the finding that labor productivity growth has been increasing over the long run, from 1770 to 1979. Romer argued that the rising world productivity growth may be due, in part, to the increasing returns to scale. It is difficult to discriminate directly between this model and the interaction hypothesis. A simple procedure is to replace $\hat{\kappa}_t^h$ with κ_t^h , the relative level of capital intensity in country h at time t (or γ_t^h , the relative level of capital stock) in equation (7a). Country and period dummy variables are also included in alternative specifications. The estimated coefficients of κ_t^h (and γ_t^h) are all statistically insignificant. Jess Benhabib and Boyan Jovanovic (1991), using U.S. aggregate data and the Summers-Heston sample, also find little evidence to support externalities to capital in a modified Romer model.

IV. Concluding Remarks

It is illuminating to recast the results in an historical frame. In 1880, the United Kingdom was the leading nation in terms of productivity and capital intensity, and the United States was second, while Italy and Japan were still in the earliest stages of industrialization. Between 1880 and 1938, despite two major depressions and a world war, modest convergence occurred in both TFP and labor productivity among the countries in the sample. The United States had by far the highest growth in capital intensity and, by 1938, had the newest capital stock, the highest capital:labor ratio (three times the average of the other countries), and the highest TFP level (45-percent greater than the average of the other countries). The United Kingdom was last in capital:labor growth and, by 1938, had slipped to third in terms of capital intensity and second in terms of TFP.

The 1938–1950 period, dominated by World War II, saw the United States surge ahead of the rest of the countries in terms of technological leadership. By 1950, the TFP level in the United States was more than twice the average of the other coun-

¹⁶However, it should be noted that the capital:output ratios have not been adjusted for changes in capacity utilization. Such an adjustment may reduce the variability in the estimated capital:output ratio over time.

tries. Moreover, absolute declines in TFP levels were recorded for Germany and Japan.

The postwar period, from 1950 to 1979, was characterized by very strong convergence in TFP, labor productivity, and capital intensity among the group of seven. Part of this process was due to the postwar recovery of Germany and Japan. However, this was also a period characterized by historically unprecedented high rates of TFP growth, labor productivity growth, and capital:labor growth. The United States maintained its technology leadership, but its relative position dwindled from more than twice the average of the other countries to a 22-percent differential. The United States had the lowest rate of capital:labor growth, and by 1979 its capital stock was 15-percent older than the other countries' and 73-percent older than Japan's.

In summary, the emergence of the United States as the technological leader in 1900 and the widening gap between the United States and rest of the world through 1950 coincides with a very high rate of capital:labor growth, its dominance in terms of capital intensity, and its new capital vintages. Its dwindling leadership position during the postwar period is coincident with low capital:labor growth and the aging of its capital stock. The loss of technological leadership by the United Kingdom after 1890 and the almost continuous slippage in its relative position thereafter is associated with a low rate of domestic investment and the relative aging of its capital stock.

Finally, the rate of catch-up of individual-country technology levels was positively associated with the rate of growth of the capital:labor ratios. However, the strength of this association varied over time and was strongest after World War II. Indeed, the regression results with the prewar data yield a positive but statistically insignificant interaction effect. These results are consistent with the results of Abramovitz (1986), who found sluggish convergence in labor productivity before World War II and rapid convergence after. He attributed the difference to the lack of "social capability," low educational levels, and inadequate industrial and

financial organization before World War I; between 1913 and 1950, the process was interrupted by two world wars and the Great Depression; and only after 1950 was the process rapid and smooth, because all the elements for the catch-up process were in place.

A strong interaction effect appears to occur when inhibitions to growth are eliminated. Such a period is characterized by high (average) productivity growth, a high rate of capital formation, a large initial dispersion of technology levels, and rapid catch-up in technology, as characterized the years from 1950 to 1979. The interaction effect is likely to be weak when impediments to growth are present or when differences in technology levels among countries are small.

Economic Forecast Evaluation: Profits Versus The Conventional Error Measures

By GORDON LEITCH AND J. ERNEST TANNER*

Economists are often puzzled as to why profit-maximizing firms buy professional forecasts when statistics such as the root-mean-squared error or the mean absolute error often indicate that a naive model will forecast about as well. This paper argues that the reason is that these traditional summary statistics may not be closely related to a forecast's profits. Using profit measures, we find only very weak relationships between such summary error statistics and forecast value. If these results are robust, then least-squares regression analysis may not be appropriate for many studies of economic behavior. (JEL C52, C10)

Economists are often puzzled as to why seemingly profit-maximizing firms buy economic forecasts. Summary statistics such as the average absolute error (AAE), the root-mean-squared error (RMSE), and the Theil "U" statistic (which is free from the dimension problems of the other two) rarely reveal major differences between professional forecasting services and a simple naive approach of no change in the variable being forecast.¹ Yet, millions of dollars are spent annually both producing and purchasing these apparently worthless forecasts.

In this paper, we argue that the conventional criteria used in these evaluations may

well be inappropriate. In empirical tests of interest rate forecasts for the 1980's, we find that the conventional criteria, based upon some measure of the size of the forecast error, have no systematic relationship to profits. Perhaps because of some embarrassing forecasts and generally poor performance on the basis of conventional criteria, few forecasters are willing to allow extensive evaluations of their historical forecasts of interest rates.² However, we did have access to the entire record of one professional service and have used it as a basis for comparison. Moreover, with interest rate forecasts, a profit measure can easily be calculated, thereby permitting tests of the relationship between profits and the conventional measures of forecast-error magnitudes. It is naturally better to examine profits directly than to examine a proxy that is at

*Graduate student and Professor, respectively, Department of Economics, Tulane University, New Orleans, LA 70118. We are grateful to Vittorio Bonomo for many insightful discussions in evaluating economic forecasts. In addition, Ron Batchelder, John Boschen, Tom Mayer, Michael Parkin, Ed Tower, Terry Wilford, Jeff Zabel and three anonymous referees offered many helpful comments on earlier drafts. However, they are not responsible for any of the paper's shortcomings.

¹Among those who accept the null hypothesis of no value added by most sophisticated forecasts over simple ARIMA-type models are Charles R. Nelson (1972), J. P. Cooper and Nelson (1975), G. V. L. Narashimhan (1975), J. R. Schmidt (1979), A. C. Petto (1981), and David Ahlers and Josef Lakonishok (1983). However, some evaluators do find that the larger models do supply valuable information not contained in the simple forecasts. See, for example, the evidence contained in Carl F. Christ (1975), Stephen K. McNees (1975, 1979), Roger Craine and Arthur M. Havenner (1988), and E. Philip Howrey et al. (1974).

²The semiannual *Wall Street Journal* survey occasionally makes mention of these problems. For example, in the July 1987 survey, it was noted that the strong economy produced sharply higher bond yields during early 1987, and many forecasts "proved widely inaccurate during the first half." A possible consequence of this was that one forecaster bowed out after predicting "anemic economic growth ... as well as a sharp decline in bond yields (July 6, 1987, p. 2) The *Blue Chip Economic Indicators* service has experienced similar difficulties as many of their interest rate forecasters do not permit identification, while all of their GNP forecasters are explicitly identified next to their forecasts.

best indirectly related to profits. Economists generally assume that firms use forecasts because they add to profits. Thus, a more appropriate test of forecast accuracy is profitability, and not the size of the forecast error or its squared value.

The paper proceeds as follows. Section I reviews the commonly used criteria to evaluate forecasts, while Section II describes a number of ways to calculate profit measures of an interest rate forecast. In Section III, we describe the interest rate forecasting approaches used in our evaluations, including the professional service and the more naive approaches. In Sections IV and V, we evaluate the forecasts in terms of the alternative profitability measures described in Section II and in terms of the conventional error-measures criteria widely used in the literature. In Section VI, we summarize the paper and offer some tentative conclusions.

I. Widely Used Forecast-Evaluation Criteria

Economic forecasts are typically evaluated by comparing the errors obtained when measuring the forecast values against the actual outcomes. The three commonly used statistics evaluating forecasts in this manner are the average absolute error (AAE), the root-mean-squared error (RMSE), and the Theil "U" coefficient.

The more familiar AAE and RMSE criteria can be misleading in certain cases. For example, a forecaster using the unit of measurement of thousands of dollars will have different error values than another forecaster using millions of dollars. Theil's U statistic is free of these problems. It can be viewed as the RMSE of a forecast divided by the RMSE of a naive forecast of no change:

$$(1) \quad U = \sqrt{\frac{\sum_{t=1}^N (\Delta F_{t+j} - \Delta A_{t+j})^2}{\sum_{t=1}^N (\Delta A_{t+j})^2}}$$

where F_{t+j} is the forecast value j periods ahead, A_{t+j} is the actual realized value of a

variable, N is the number of forecasts, $\Delta F_{t+j} = F_{t+j} - A_t$, and $\Delta A_{t+j} = A_{t+j} - A_t$. $U = 0.0$ when the prediction is perfect, $U = 1.0$ when the RMSE of the predicted change equals the accuracy of the baseline forecast of no change, and statistics greater than 1.0 indicate that the forecasts have higher RMSE's than the no-change forecast. Because of the appeal of least squares based on a quadratic loss function, in which larger errors receive proportionately more weight, the RMSE and the Theil U coefficient have been the most popular criteria in the literature.³ Other criteria have been proposed, but cataloging them would be a distraction.

II. Profit Measures of Using an Interest Rate Forecast

While there are many ways to calculate profits for an interest rate forecast, most alternatives cannot be studied, because the data are not available. For example, while the professional service's forecasts that we studied were issued monthly for 14 interest rates covering each of the succeeding 12 months,⁴ few of these interest rates are represented by a corresponding forward rate and a futures contract. An exception, the three-month Treasury bill rate, has received the most attention in the literature. Since there is a liquid futures market for this security, we analyzed only this rate in our

³We know of one prominent forecaster who purposely was pessimistically biased in his forecasts. Because he believed that the profit-maximizing firms wanted to protect themselves from the "worst-case scenario," his forecasts were purposely biased. Clearly, since he believed that his clients' loss functions were not symmetrical, the conventional criteria would not be appropriate for judging the accuracy of his forecasts. The implications of this forecaster's beliefs have much more significance, for if he is correct, then least-squares regression analysis may not be appropriate for many empirical studies of economic behavior.

⁴The monthly forecasts on 14 interest rates for the period 1-12 months ahead are done by the Commonwealth Research Group and released through the *Money Rate Report* on the final trading day of each month. We should note that one of the authors is a cofounder of this firm and retains a financial interest in it.

tests. Moreover, this is one of the interest rates for which we had access to a monthly survey of money managers, economists, corporate treasurers, and other forecasters up to a year ahead of each of the futures contract months (March, June, September, and December).

Even narrowing the available data set to this extent leaves many measures of profit available. Are profits calculated from the cash market, the futures market, or the forward market? What is the size of the position assumed, and does it change depending upon the forecast? What are the transaction costs including brokers' fees and bid-ask spread?

To simplify matters, but to preserve the maximum level of realism corresponding to that for a user of interest rate forecasts, we did our profit calculations in the futures market for Treasury bills. We assume that the size of the position is always one unit;⁵ all transactions were executed at the closing price at the end of the month,⁶ when the

professional service's forecasts became available; and the positions were always evaluated at one-month intervals. New positions, based upon the updated forecasts, were assumed to have been taken at the closing price of each month.

For trading in Treasury-bill futures, round-trip broker's fees would range from about \$8.50 each for large traders to about \$85.00 for full-service retail brokers. The initial margin requirement for trading the \$1 million Treasury-bill contract is set by the broker and usually ranges between \$2,000 and \$2,500, but falls to \$1,500 at most brokers for maintenance purposes. To deal in such a contract, the usual procedure is to deposit with the broker between \$10,000 and \$20,000 in a money-market fund earning a competitive short-term interest rate. As one trades, funds are removed from and deposited to the trading account as needed. Thus, for most practical purposes, the \$2,000–\$2,500 margin earns no interest while the rest of the funds earn a competitive rate of return. If the market moves unfavorably, funds are transferred from the money-market fund to the trading account in order to meet the maintenance margin. However, should the market move in a favorable direction, excess funds will be pulled from the trading account and placed in the money-market fund earning additional interest. No interest will be earned on the maintenance margin required to hold the position in a "speculation" account. However, the same is not true for hedgers who have lower margin requirements.

In short, if a nonhedger uses a discount broker and the market fluctuates randomly, then round-trip costs amount to about \$40 per month (\$25 broker's fees and \$15 lost interest on \$2,000) to speculate on the price change of a single \$1 million Treasury-bill futures contract. In our tests, and in actual practice, the transactions costs would be less, because we assumed new trades only when the new forecast calls for one to reverse positions or to roll over from an expiring contract.

In this environment, there are still many ways to use an interest rate forecast. Our approach for the first profit calculation

⁵Vittorio Bonomo (1989) finds that professional commodity-market traders do not vary the size of their bet, but amateurs, who end up as losers, do vary the size of their positions. He argues that if the odds are in one's favor, a series of constant-sized bets virtually guarantees success, and the professionals profit by making a large number of bets so that the odds work for them. On the other hand, traders who lose their money tend to assume different-sized bets over time. This result is obvious if one thinks of "doubling up" when the odds get high. In this case, unless the forecast is certain, such a strategy eventually always would result in losing money. For counterexamples to Bonomo's assertions, see Richard A. Epstein (1977 Ch. 3). In the context of a log utility function, a strategy of proportional betting, in which the size of the bet is proportional to expected profits, could dominate the constant-bet strategy we use. Such a strategy may make profits more highly correlated with the RMSE criterion.

⁶For most traders, placing a buy or sell "on-close" order would not have any appreciable effect on price. Given our assumption of one contract, it is very unlikely that our profit calculations would be materially affected by the effect such an order would have on this relatively fluid market. In fact, our broker at Shearson says there is a 99-percent probability of a fill at this price as several thousand contracts were traded on a typical day during the sample period used. Thus, the assumption that fills are done at closing prices gives the most accurate *ex post* prices available.

(profit-rule A) was straightforward: if interest rates are forecast to rise, go "short" or sell a futures contract; conversely, if rates are forecast to fall, go "long" or buy a futures contract. This approach implicitly assumes that the market does not expect interest rates to change. On a \$1 million three-month Treasury bill, each basis-point change in the interest rate changes the gross return by \$25 ($\$1 \text{ million} \times 0.01 \text{ percent} \times 0.25 \text{ years}$). Thus, for each basis-point change in interest rates on the futures contract, the price of the contract changes by \$25. Gross returns, before costs, are calculated directly using \$25 per basis-point change and the position taken. A \$15 opportunity cost on the margin funds per month and \$25 per round-trip trade were then subtracted to obtain trading profits.

Our second profit calculation (profit-rule B) is similar but takes the futures-market forecast explicitly into account. This profit calculation assumes that, if interest rates are forecast to be above the rate implied by the futures market, one will short the contract; and conversely, if rates are expected to be below the rate implied by the futures contract, one will go long the contract. After this position is taken, profits are calculated in the same manner as above.

Our third profit calculation (profit-rule C) assumes a position only if interest rates are expected to change. If the forecast is for no change in rates (saying one doesn't know what to do), then the action is not to take a position. Otherwise, positions are assumed as in the second profit calculation above by comparing the forecast with the market's forecast.

Our fourth profit calculation (profit-rule D) assumes a position only if the forecast change in interest rates is opposite in sign to that of the market's forecast change. In other words, we take a long position in the futures contract only if we forecast rates to fall while the futures market is forecasting a rise, and conversely. At other times, no position is taken.

Because the professional interest-rate-forecasting service offers a prediction of the three-month Treasury bill rate for each of the next 12 months, we could theoretically

estimate profits for each of the 12 forecast horizons. However, because we wanted to use the Treasury-bill forward market as an alternative forecasting system, we used only the forecasts up to nine months ahead. This is because the longest-maturing cash Treasury bill is only for one year. As a result, the longest readily estimated forward rate for three-month Treasury bills is nine months.

In predicting ahead nine months for the forecasts, we matched the forecast month with the nearest contract that would not expire before the end of the month (e.g., the December, January, and February forecasts were matched with the March futures contract; the March, April and May forecasts were matched with the June contract). Depending upon the current month, this means that the nearest three or the nearest four contracts are traded.

III. Forecasting Systems

For the tests made in this paper, we employed seven different forecasting systems. The first forecasting system was based upon the professional service whose forecasts were published in the *Money Rate Report*. Although the complete set of forecasts started in 1980, we only used the period beginning with their year-end 1981 forecast. At that point, the service began consistently including executive survey forecasts for interest rates. The survey, usually done during the last 10 days of the month, provides a "consensus" forecast for the three-month Treasury-bill rate for each month of the futures contracts up to a year ahead and fits well with our tests. Upon introducing the survey, the service indicated that the survey respondents included "[c]orporate financial officers, banking executives, and operating heads of firms ... [because] many analysts feel that market derived forecasts do not fully nor accurately represent informed opinion as to the future course of interest rates ..." (*Money Rate Report*, January 1981, p. 1). Because the survey results for the three-month Treasury bill rate were available monthly only since year-end 1981, we use the sample period from January 1982 through December 1987 for our tests.

The other forecasting systems are more conventional. An ARIMA model was estimated initially over the seven-year period beginning in January 1975 and ending in December 1981. The structure of the one-month change in three-month Treasury-bill interest rate appeared to be of the form AR(2). The fitted initial equation was estimated to be

$$(2) \quad r_t = 0.337 + 1.220 \text{ 3MoTBill}_{t-1} \\ (1.00) \quad (10.16) \\ -0.255 \text{ 3MoTBill}_{t-2} \\ (2.06)$$

($R^2 = 0.886$). For the purposes of the tests in this paper, we used a rolling regression with a fixed beginning point but ending with the month in which the above forecasts were made. Thus, aside from the general structure, only information available in the marketplace at the time the positions were assumed to have been taken was used in our *ex post* ARIMA forecasts. The final one-month-ahead ARIMA-forecast equation, estimated from January 1975 until December 1987 and looking very similar to the initial equation, was

$$(3) \quad r_t = 0.387 + 1.133 \text{ 3MoTBill}_{t-1} \\ (1.91) \quad (14.25) \\ -0.181 \text{ 3MoTBill}_{t-2} \\ (2.27)$$

($R^2 = 0.918$). This methodology was followed for the other forecast horizons using the ARIMA technique.

For the forward rate, we used the end-of-month Treasury-bill yield curve, as reported in the *Wall Street Journal*. The implicit rate up to nine months ahead for the three-month Treasury-bill rate was estimated from the Treasury-bill yield curve's bid price using the appropriate maturity dates up to one year ahead.

The futures rate forecasts were derived from the historical prices of the four nearest Treasury-bill future contracts. For forecasts nearer than the nearest contract, we interpolated between the current spot rate and the rate implied by the nearest contract.

For forecast dates between contract dates, we interpolated between the implied forecasts of the adjoining contract dates.

The other two forecasting systems are the naivest of models. The "naive no-change" technique forecasts that all future rates will equal the current spot rate. The "constant rate of growth" technique forecasts that the change in interest rates over the next x months is compounded from the most recent one-month change. Thus, rising interest rates are expected to continue to rise, while falling rates are expected to continue to fall.

IV. A First Look at the Data for Economic Forecasts: Profits and Other Criteria

In most evaluations of economic forecasts, profits are totally ignored. In Table 1, we present summary figures on the six-year average for the nine forecast horizons using the six forecasting techniques. The profitability of the forecast appears to bear little relationship to the conventional size-of-error criteria.

For the purpose of the table, we assumed that any forecast for interest rates to rise was associated with selling the appropriate futures contract and any forecast for interest rates to fall involved buying the contract. The no-change forecast involved sitting on the sidelines. Thus, the naive no-change forecast produces no profits or losses. As described in Section II, profits were calculated using the four nearby contracts corresponding to interest rate forecasts up to nine months ahead. We will show later that the lack of a clear relationship between profits and the conventional criteria is not due to the way we calculated profits, as all profit-calculation methods produced similar results. First, we need to explain what we did more fully.

The column labeled "average directional accuracy" shows the percentage of interest rate changes in the futures market that were accurately forecast by each technique over the one-month observation interval until the new forecasts were available. The results are not surprising because the forecasts are predicting revisions in what is essentially the market's full-information forecast. If the

TABLE 1—PROFITS AND OTHER FORECAST-EVALUATION CRITERIA, JANUARY 1982–DECEMBER 1987

Forecasting technique	Six-year average annual profits	Average directional accuracy (percentage)	Average absolute error (percentage)	Average root-mean-squared error (percentage)	Average Theil <i>U</i> statistic
Professional service	\$1,643	49.3	0.781	0.932	1.93
ARIMA	–\$928	47.9	0.739	0.902	1.82
Forward rate	–\$3,050	43.7	0.656	0.848	1.62
Naive no-change	\$0	37.9	0.410	0.530	1.00
Constant rate of growth	–\$674	46.6	2.013	2.514	4.72
Survey forecast	–\$3,262	43.8	0.811	1.081	2.06

Profit Rule

Buy a \$1 million Treasury-bill futures contract if interest rates are forecast to fall, and sell a contract if rates are expected to rise. Profits are calculated based on a \$25-per-basis-point change in the futures contract over a one-month period, until a new forecast is made at the close of each month.

Note: Although the level of profits, directional accuracy, and size of forecast error are different depending on the profit rule, the general pattern is very similar across trading rules, and in no case does there seem to be a strong and theoretically correct relation between profits and the error criteria. Thus, for brevity, we summarize the data using profit-rule A, as it seems to be the most straightforward.

interest-rate market is efficient, which most studies find it to be, then predicting changes in interest rates by any system should be equivalent to flipping a coin. The possible exception is the naive no-change forecast, which predicts that the futures market rate will move toward the spot rate. The fact that it appears to forecast the wrong direction almost two-thirds of the time suggests that the spot rate probably moves to the futures market, rather than conversely, but that is not the subject of this paper.⁷

The “average absolute error” column is the average difference between the forecast value as made at the end of the previous month and the futures-market value at the end of the current month for the forecast month in question. Note that, instead of the actual realized interest rate, we have used only the next month’s new futures-market forecasts for the realization in this table. However, the results are not affected by doing the calculations this way, as the cash markets give essentially identical results. The root-mean-squared error and the Theil *U* statistics are calculated from the same

month-end data of the futures market and forecasts.

The data presented in this table are consistent with previous research. The only reference to a profit criterion that we find in the literature suggests that profits do not appear to be related to lowest root-mean-squared error. In Stephen Figlewski and Thomas Ulrich (1983), profits of a Treasury-bill forecast, when corrected for bias, are directly related to the size of the forecast error; but when they are not corrected for bias, profits and error measures are inversely related. However, the authors do not draw attention to this aspect of their research. Similarly, Scott Hein and Raymond Spudeck (1988) find no relation between cost and the conventional error criteria; but since they are concerned with using forecasts to minimize interest borrowing costs, they ignore the implications for forecast evaluation.

The columns on the size of the forecast error are also consistent with previous research; that is, in general, the smaller the forecast error, the better the Theil statistic. Moreover, as in the findings of James Pesando (1978), the naive forecast of no change has the smallest error, followed by predictions based on the forward rate and the ARIMA model. The worst forecasts, ranked from worst to best in terms of error magnitudes, are the constant-interest-rate-change forecasts followed by the survey forecasts, and then the professional-service forecasts.

⁷Michael T. Belongia (1987) found similar results for the cash market in Treasury bills. Using the results of the professional forecasters surveyed semiannually by the *Wall Street Journal*, he found they had an accuracy rate of 42 percent in predicting the direction of change over a six-month horizon. The comparable rate for the futures market was 55 percent.

TABLE 2—CORRELATIONS BETWEEN PROFITS AND THE VARIOUS FORECAST CRITERIA FOR TREASURY-BILL FUTURES MARKET TRADING AVERAGED OVER FORECAST HORIZONS OF 1–9 MONTHS

Profit rule	DA		AAE		RMSE		Theil <i>U</i>	
	<i>r</i>	<i>t</i>	<i>r</i>	<i>t</i>	<i>r</i>	<i>t</i>	<i>r</i>	<i>t</i>
A	+0.428	2.76	–0.077	0.45	–0.094	0.55	–0.156	0.92
B	+0.842	9.11	+0.185	1.10	+0.210	1.25	–0.230	1.38
C	+0.598	4.35	+0.226	1.35	+0.253	1.52	–0.148	0.87
D	+0.578	4.13	+0.326	2.01	+0.322	1.99	+0.009	0.05

Profit Rules

- A: forecast rates to rise, short the futures contract; forecast rates to fall, buy the futures contract
 B: forecast rates to be above implied forecast of futures, go short; forecast rates to be below implied forecast of futures, go long.
 C: same as B, except no position if forecast is for no change in rates
 D: take position only if forecast change has opposite directional sign to market forecast.

Notes: DA = directional accuracy of forecast; AAE = average absolute error of forecast; RMSE = root-mean-squared error of forecast; Theil *U* = Theil's forecast-evaluation statistic; *r* = simple correlation coefficient; and *t* = absolute value of the *t* statistic on the slope coefficient. For all analyses, *N* = 36 (forecasts for all nine forecast horizons were grouped together in each year, yielding six years of data on six forecasting systems, or 36 observations per profit rule).

Based upon the usual error-magnitude criteria, the results of this table confirm the major conclusions of the literature that firms appear to waste money on economic forecasts.

However, if profits were the criterion for whether or not to purchase forecasts, then the conclusion might be different. In the case summarized in Table 1, the only profitable system finished fourth out of six, based on the conventional criteria. There is nothing in these "error" criteria that would have caused firms to choose this profitable forecasting technique over the others. Yet, since the profitable forecasts were available only at a price while the others were essentially free, the market test did indicate that this forecast service's clients were probably not using the economists' criteria of lowest mean absolute error to evaluate the forecasts.

V. Statistical Relationships Between Profits and Error Measures

Although these results, which were based on six-year averages for one relatively arbitrary use of interest rate forecasts, are interesting and informative, are they statistically

significant, and do they hold up for other plausible ways of using interest rate forecasts? To answer these questions, we calculated correlations between the various criteria and profits as measured by each of the profit rules discussed in Section II.

In Table 2, we present the results of averaging each forecast system over all nine forecast horizons for each year. Thus, the data are based on 36 observations: six forecasting systems for six years. In Table 3, we present the results for each of the nine forecast horizons. Since the data are still averaged over each year, we have 324 observations, corresponding to the six forecast systems and nine forecast horizons over six years.

As Table 2 shows, regardless of the profit rule followed, there is little systematic relationship between profits and the conventional measures of forecast quality. The only conventional measure of forecast quality that is related to profits is "directional accuracy" (DA), and it is infrequently used.⁸

⁸To the best of our knowledge, only James Cicarelli (1982) and E. Philip Howrey et al. (1974) use direc-

TABLE 3—CORRELATIONS BETWEEN PROFITS AND VARIOUS FORECAST CRITERIA FOR TREASURY-BILL FUTURES-MARKET TRADING AVERAGED OVER EACH YEAR BUT WITH EACH OF THE NINE FORECAST HORIZONS TREATED SEPARATELY

Profit rule	DA		AAE		RMSE		Theil <i>U</i>	
	<i>r</i>	<i>t</i>	<i>r</i>	<i>t</i>	<i>r</i>	<i>t</i>	<i>r</i>	<i>t</i>

D	+0.572	12.51	+0.212	3.90	+0.216	3.97	-0.038	0.68

Profit Rules

- A: forecast rates to rise, short the futures contract; forecast rates to fall, buy the futures contract.
 B: forecast rates to be above implied forecast of futures, go short; forecast rates to be below implied forecast of futures, go long.
 C: same as B, except no position if forecast is for no change in rates.
 D: take position only if forecast change has opposite directional sign to market forecast.

Notes: DA = directional accuracy of forecast; AAE = average absolute error of forecast; RMSE = root-mean-squared error of forecast; Theil *U* = Theil's forecast-evaluation statistic; *r* = simple correlation coefficient; and *t* = absolute value of the *t* statistic on the slope coefficient. For all analyses, *N* = 324 (six forecasting systems, nine horizons, and six years of data).

The standard criteria show no consistent relationship with profits. Indeed, the average-absolute-error and root-mean-squared-error criteria have perverse signs (better forecasts should have lower average errors and higher profits, and thus, the simple correlations should be negative) in three-quarters of the cases. While the Theil statistic has the correct sign in three cases out of four, it is never statistically significant at conventional levels of significance.

Increasing the data set to 324 observations by treating each forecast horizon separately, but still averaging the data over the year, produces similar results (Table 3). However, the sizes of the error criteria are now occasionally significantly related to profits. However, of the six statistically significant correlations, three have incorrect signs. Nevertheless, directional accuracy re-

mains highly significant as a proxy for forecast profits.

In Table 4, we present the correlations and related absolute *t* values between the conventional criteria using profit rule B. For brevity, the other profit rules have been omitted, but the results are very similar. As we would expect based upon the earlier tables, directional accuracy and the error-measure criteria are only weakly related. However, the various error-measure criteria are all closely related, confirming the usual result that the accuracy of the forecast is not likely to be dependent upon which error criterion is used. Unfortunately, none of the error criteria is reliably related to the profitability of the forecast.⁹

tional accuracy in evaluating forecasts. While Cicarelli was proposing the criterion, rather than extensively evaluating forecasts, Howrey et al. were using it to bolster the record of the Wharton forecasts over the 1969–1970 recession.

⁹Because many previous studies used professional forecasts in comparisons with the ARIMA-type forecast, we have followed their example. However, in the present case, it is conceivable that our results depend upon some fortunate outliers of the particular professional forecasting service we used. To test this conjecture, we redid the tests excluding the forecasts of the professional service. In this reduced sample, all the correlation coefficients and all the *t* values were extremely close to those reported in Tables 2, 3, and 4.

TABLE 4—CORRELATIONS AMONG VARIOUS FORECAST CRITERIA

N	Statistic	Correlation					
		DA-AAE	DA-RMSE	DA-Theil U	AAE-RMSE	AAE-Theil U	RMSE-Theil U
36	<i>r</i>	+0.061	+0.077	-0.129	+0.997	+0.675	+0.657
	<i>t</i>	0.36	0.45	0.76	71.83	5.33	5.08
324	<i>r</i>	+0.012	+0.024	-0.104	+0.996	+0.744	+0.726
	<i>t</i>	0.22	0.42	1.88	202.7	19.96	18.92

Notes: DA = directional accuracy of forecast; AAE = average absolute error of forecast; RMSE = root-mean-squared error of forecast; Theil U = Theil's forecast-evaluation statistic; *r* = simple correlation coefficient; and *t* = absolute value of the *t* statistic on the slope coefficient.

Since the forecasts we have used pertain to the cash market, conclusions based on the futures market about the reliability of conventional forecast-evaluation criteria may be flawed, because the two markets do not track exactly. As a consequence, we redid the tests using the cash market. In doing so, we were forced to make some very severe and unrealistic assumptions. First was the obvious problem that any three-month Treasury bill automatically turns into a two-month Treasury bill over the one-month observation interval. To overcome this problem, we assumed a perpetual three-month Treasury bill. With this theoretical construct, profits were calculated by multiplying \$25 by the change in the three-month bill rate. Second, opportunity and trading costs in the cash market can differ widely, depending upon the characteristics of the trader, such as the bid-ask spread or the "cost of carry." To avoid these problems, we assumed trading costs identical to those applicable to futures trading with all transactions being made at the "bid" price.

While these assumptions are limiting, they do allow an operational method with which to calculate profits in the cash market, and the results are essentially identical to those derived from using the futures market. Profits and the directional accuracy of the forecast systems are highly correlated with a high degree of statistical significance. However, the relationships between profits (or directional change) and the conventional size-of-forecast-error criteria appear to be

very poorly related. In just over half the experiments tried, the relationships between profits and the root-mean-squared error have the anticipated correct negative sign; but individually, the level of significance is higher for the theoretically incorrect positive signs than for the correct negative signs. Like the futures-market evaluations, only the Theil *U* statistics generally have the theoretically appropriate signed relationship to profits, but often the level of significance is less than satisfactory as a reliable forecast-evaluation criterion.

VI. A Tentative Conclusion

Forecast evaluations made on the basis of conventional error-magnitude criteria often find little justification for profit-maximizing firms to allocate resources to professional forecasters, as naive models often predict as well. Unfortunately, the size of the conventional forecast-error criteria frequently has unpredictable relationships to the forecasts' profitability, rendering these criteria unreliable indicators of profits. Indeed, in evaluating the quality of interest rate forecasts, where forecast profits are readily calculated, we find no systematic relationship between the widely used *ex post* error criteria and *ex post* profits. The only substitute criterion for profits found in the literature that appears to be closely related is directional accuracy. The relationship between directional accuracy and profits appears to be almost as close as the relationships of the

various error criteria are to each other. However, because the root-mean-squared error, the average absolute error, and the Theil U statistic appear to be tenuously linked to profits and directional accuracy, it is not surprising that profit-maximizing firms buy forecasts in spite of their seemingly large forecast errors.

The results of this paper suggest that, if profits are not observable, directional accuracy of the forecasts might be used as the evaluation criterion. All the conventional forecast-error-magnitude criteria are only marginally related to profitability, while directional accuracy consistently demonstrates a high degree of statistical association.

A more disturbing implication of our findings is that conventional least squares may not be the appropriate estimation technique for economic behavior. If profits are not related to the size of the error, then it may be that our empirical estimates of economic relationships should not be based upon a squared error loss function.

The Stock Market Premium, Production, and Relative Risk Aversion

By SIMON BENNINGA AND ARIS PROTOPAPADAKIS*

Higher relative risk aversion (RRA) is associated with higher risk premiums only if the riskiness of output is exogenous. When consumers can affect the variability of output, the market risk premium may well decrease as the RRA increases. With constant relative risk aversion and linear production functions, the ratio of the market risk premium to the standard deviation of the market is constant and independent of the RRA. (JEL D20, D80)

Suppose it is possible to observe two economies in equilibrium. In each economy, consumption and production decisions are made by a representative consumer. Suppose that all aspects (production possibilities, initial endowments, etc.) of the two economies are the same, except that the relative risk aversion, henceforth RRA, of the representative consumer in one economy is larger than the RRA of the second economy's representative consumer. In which economy would the equilibrium stock market risk premium be larger?

The intuitive and appealing answer is that the economy with the larger RRA would exhibit the larger market premium. This answer derives in part from the intuition given in papers by David Cass and Joseph E. Stiglitz (1970, 1972) and Peter A. Diamond and Stiglitz (1974), which show

that, given a choice between one risky and one riskless asset, a consumer with higher RRA will choose a less risky portfolio than a similar consumer with a lower RRA. Indeed, most researchers who have tried to measure the average RRA use models whose first-order conditions formalize this intuitive answer. Some examples are Irwin Friend and Marshall E. Blume (1975), Irwin Friend and Joel Hasbrouck (1982), Lars Peter Hansen and Kenneth J. Singleton (1983a,b), Roger-A. Morin and Antonio Fernandez Suarez (1983), Varouj A. Aivazian et al. (1986), Robert H. Litzenberger and Ehud I. Ronn (1986), and George G. Szpiro (1986).

In this paper, we show that the extension of the Cass-Stiglitz results to the general equilibrium pricing of risk can be problematic. Aggregating individual portfolio choices will reveal little about the price of market risk, because a shift in demand from risky to risk-free assets in general will cause the price of the risky asset to rise and that of the risk-free asset to fall. Therefore, the effect on the market risk premium is unclear. However, if the aggregate risk is assumed to be exogenous, then it follows that an economy with a larger RRA will exhibit a larger market risk premium.

While it is natural to assume that the micro risk-return trade-offs are exogenous to individuals' portfolio choices, taking the economy-wide risk-return trade-off as fixed is a much more questionable assumption. For instance, Roger C. Kormendi and Philip

G. Meguire (1985) report that the range of output growths observed across countries can be described as choices made from a risk-return frontier: the cost of higher growth is higher variability of output. At the macro level, production is not exogenous, and utility-maximizing economic actors can choose, at least to some extent, the variability of output. When this choice of production variability is taken into account, we demonstrate that it need not follow that higher RRA is associated with a higher risk premium.

In particular, we show that in an economy of a representative consumer with a constant RRA utility function and with linear but risky production possibilities, the equilibrium market risk premium decreases as the RRA increases if the consumer can affect the variability of output. If she cannot, then the market risk premium increases as the RRA increases.

In Section I, we present our basic model. Section II discusses the case of linear production. In Section III, we discuss some implications of the results for the market return:risk ratio; we also discuss how production-function curvature may cancel the effect of utility-function curvature on the riskiness of output.

I. The Model

Throughout the paper we discuss a two-date model.¹ At date 0, the consumer chooses consumption for the current period and inputs which will be used to provide (through a production technology) consumption at date 1. Uncertainty is modeled by assuming that at date 1 one of two states occurs and that the output provided by the production technologies is state-dependent.

We wish to distinguish between *complete* and *incomplete* production technologies. A complete production technology allows the consumer to choose separately the total output in each of the two states occurring at date 1. An incomplete production technol-

ogy does not allow this separation.² Suppose state 1 at date 1 is a "bad" state of the world and state 2 is a "good" state ("good" and "bad" in the sense that the same input will produce more output in the good state than in the bad state). In a complete production technology environment, the consumer can choose the ratio of consumption in the bad state to that in the good state. Thus, the consumer can choose the date-1 variability of her consumption. In an incomplete production environment, the consumer cannot do this: more consumption in the bad state will necessarily mean more consumption in the good state also.

We show that the ability of the consumer to choose consumption variability is a critical factor in determining whether increasing relative risk aversion implies a greater or lesser market risk premium. Although this claim may be illustrated under general conditions, the underlying intuition is most easily grasped in a model with linear production functions. In the next section, we discuss such a model. Before doing so, however, we set out the two cases and derive the first-order conditions.

A. The Complete-Production-Technologies Case

With complete production technologies, the consumer maximizes the utility of consumption today, c_0 , and expected consumption in states 1 and 2 tomorrow, c_1 and c_2 , subject to the following constraints:

$$(1a) \quad \max[EU(c_0, c_1, c_2)] = U(c_0) - \delta\{\pi U(c_1) + (1 - \pi)U(c_2)\}$$

²The standard Arrow-Debreu definition of completeness stresses the ability of consumers to use financial markets to decompose vectors of state-dependent returns into their basis vectors (cf. Gerard Debreu, 1959; Kenneth Arrow, 1964) and to price these basis vectors separately. With a single representative consumer making economy-wide choices, this ability to separate consumption can be achieved only if it exists in the aggregate. Our definition represents an extension of the standard terminology to an economy with production.

¹The results of the paper remain the same in a multiperiod version of the model.

subject to

$$(1b) \quad c_0 = W - z_1 - z_2$$

$$(1c) \quad c_1 = \alpha f(z_1)$$

$$(1d) \quad c_2 = \beta f(z_2).$$

At date 0, the consumer chooses inputs z_1 and z_2 of the model's single physical good. These inputs are used to produce $\alpha f(z_1)$ and $\beta f(z_2)$ at date 1 in states 1 and 2, respectively.³ We assume that the production function is increasing and weakly concave ($f' > 0$, $f'' \leq 0$). We further assume that $\pi\alpha < (1-\pi)\beta$, so that state 1 at date 1 is the bad state and state 2 is the good state. The parameter δ is the consumer's pure time-preference factor. Throughout the paper we look at an isoelastic utility function:

$$(2) \quad U(x) = \frac{x^{1-\gamma}}{1-\gamma} \quad \text{for } \gamma \neq 1$$

$$U(x) = \log(x) \quad \text{for } \gamma = 1.$$

The consumer's relative risk aversion is $-xU''(x)/U'(x) = \gamma$.

The first-order conditions for this problem are

$$(3) \quad q_1 = \frac{\delta\pi U'(c_1)}{U'(c_0)} = \frac{1}{\alpha f'(z_1)}$$

$$q_2 = \frac{\delta(1-\pi)U'(c_2)}{U'(c_0)} = \frac{1}{\beta f'(z_2)}.$$

The marginal rates of substitution (adjusted for probability and time preference) q_1 and

q_2 are the consumer's equilibrium valuations of one unit of the good, contingent on the occurrence of state 1 or state 2, respectively. These state prices may thus be used to price securities with state-contingent payoffs at date 1. It follows that the *risk-free rate* in the economy is $r_f \equiv 1/(q_1 + q_2) - 1$. The *present value of the market's output* is $PV \equiv q_1\alpha f(z_1) + q_2\beta f(z_2)$. The *expected value of the market's future output* is $EV \equiv \pi\alpha f(z_1) + (1-\pi)\beta f(z_2)$. The *expected return on the market* is $ER_M \equiv EV/(z_1 + z_2) - 1$, and the *market risk premium* is $RP \equiv ER_M - r_f$.

B. The Incomplete-Production-Technologies Case

We contrast the simple case given above with the case in which the consumer has the choice about how much to invest but cannot affect the variability of her future consumption.⁴ We model this case by assuming that there is a single production technology which produces, with different efficiencies, in each of the two states. Formally, the consumer maximizes

$$(4a) \quad \max[EU(c_0, c_1, c_2)] = U(c_0) + \delta\{\pi U(c_1) + (1-\pi)U(c_2)\}$$

subject to

$$(4b) \quad c_0 = W - z$$

$$(4c) \quad c_1 = \alpha f(z)$$

$$(4d) \quad c_2 = \beta f(z)$$

where, as before, $f(z)$ is weakly concave and increasing.

³The assumption that none of the z_i is productive in state j ($i, j = 1, 2$) is an inessential simplifying assumption; what is crucial to our results is that the productivity of z_i is less than z_j in state j . The results hold for more complex linear production technologies, which produce in both states of the world, as long as these technologies span the desired consumption point, thus admitting an unconstrained (non-corner-solution) optimum.

⁴For example, in the macroeconomic literature, researchers typically introduce uncertainty by specifying a production function of the form $y_t = f(k_t) + \epsilon_t$. This specification is equivalent to assuming that consumers cannot affect the riskiness of output; this holds even if the equations are in logs, in which case the error term multiplies the quantities in levels.

The first-order condition for this problem is

$$(5) \quad \frac{\delta\{\pi\alpha U'(c_1) + (1-\pi)\beta U'(c_2)\}}{U'(c_0)} = \frac{1}{f'(z)}.$$

As before, the state prices q_1 and q_2 are the probability and time-discount adjusted marginal rates of substitution, $\delta\pi U'(c_1)/U'(c_0)$ and $\delta(1-\pi)U'(c_2)/U'(c_0)$, respectively. The expected return on the market for this case is $ER_M = [\pi\alpha f(z) + (1-\pi)\beta f(z)]/z - 1$. The definitions for the riskless rate of interest and the market risk premium remain unchanged.

II. The Case of Linear Production Functions

In this section, we consider the two models set out above for the special case when $f(z)$ is linear and passes through the origin [i.e., $f(z) = z$].

A. The Complete-Markets Case

The first model we consider is one in which production technologies are complete. Thus, the representative consumer can choose the ratio of state 1 to state 2 consumption at the second date. Rewriting the first-order conditions gives

$$(6a) \quad (\delta\pi\alpha)^{1/\gamma}(W - z_1 - z_2) = \alpha z_1$$

$$(6b) \quad [\delta(1-\pi)\beta]^{1/\gamma}(W - z_1 - z_2) = \beta z_2.$$

Letting $X = (\delta\pi\alpha)^{1/\gamma}$ and $Y = [\delta(1-\pi)\beta]^{1/\gamma}$, the solution to these equations is given by

$$(7) \quad z_1 = \frac{\beta X W}{\alpha\beta + X\beta + \alpha Y}$$

$$z_2 = \frac{\alpha Y W}{\alpha\beta + X\beta + \alpha Y}.$$

THEOREM 1: *When the production function is linear and passes through the origin, the market risk premium declines as γ increases.*

PROOF:

It follows from the assumptions of the theorem that the risk-free rate is independent of the inputs and is given by $r_f = 1/[1/\alpha + 1/\beta] - 1$. One plus the expected return of the market is given by

$$(8) \quad 1 + ER_M = \frac{\pi\alpha z_1 + (1-\pi)\beta z_2}{z_1 + z_2}$$

$$= \frac{\alpha\beta[\pi X + (1-\pi)Y]}{X\beta + \alpha Y}.$$

Differentiating equation (8) with respect to γ (ignoring the $\alpha\beta$ terms and the denominator of the derivative) gives that $dRP/d\gamma$ is proportional to

$$(9) \quad [\alpha\pi - (1-\pi)\beta] \left[-1/\gamma^2 \right]$$

$$\times XY \{ \ln[\delta\pi\alpha] - \ln[\delta(1-\pi)\beta] \}$$

which is always negative.

The intuition behind Theorem 1 is the following: as the RRA is raised, the consumer wishes to make the variance of the consumption smaller. She does this by increasing the ratio z_1/z_2 . This has the effect of shifting resources to the relatively inefficient production process, and it reduces the average return on investment and with it the total market return. Since the risk-free rate in the complete-markets model is independent of the consumer's maximization (due to the linear technology), it follows that the market risk premium must fall. Another way to see this is to notice that the consumer can vary the ratio of the maximum quantity of the risk-free asset to her total wealth. The maximum quantity of the risk-free asset is $\alpha z_1/(1+r_f)$, since $\beta z_2 > \alpha z_1$. As she becomes more risk-averse, the consumer demands (and gets) more of the risk-free asset at the cost of a lower average return on her investment.⁵

⁵A useful decomposition of the representative consumer's portfolio is that it contains a risk-free asset with payoffs αz_1 in both states, whose value is $\alpha z_1/(1+r_f)$, and also contains an option whose payoff

$$(13) \quad \frac{d[q_1 + q_2]}{d\gamma} = \frac{[\pi\alpha^{1-\gamma} + (1-\pi)\beta^{1-\gamma}][-\pi\alpha^{-\gamma}\ln(\alpha) - (1-\pi)\beta^{-\gamma}\ln(\beta)]}{[\pi\alpha^{1-\gamma} + (1-\pi)\beta^{1-\gamma}]^2} \\ - \frac{[\pi\alpha^{-\gamma} + (1-\pi)\beta^{-\gamma}][-\pi\alpha^{1-\gamma}\ln(\alpha) - (1-\pi)\beta^{1-\gamma}\ln(\beta)]}{[\pi\alpha^{1-\gamma} + (1-\pi)\beta^{1-\gamma}]^2}$$

In a partial-equilibrium framework, Cass and Stiglitz (1970, 1972), Diamond and Stiglitz (1974), and Friend and Blume (1975) show that, when an individual consumer's RRA increases, the proportion of the risky asset held in the consumer's portfolio will decrease. The implications of this result for the market risk premium are unclear, since the shift in asset demand will tend to raise the price of the risk-free asset and lower the price of the risky asset. Theorem 1 shows that, if the economy can be modeled by a representative consumer and complete production technologies, the risk premium declines.

B. The Incomplete-Markets Case

In the incomplete-markets case with a linear production function, the input of z at date 0 will produce output of αz in state 1 and output of βz in state 2 of the next period. There is no possibility for the consumer to alter the ratio of consumption in the two states. One plus the expected return on the market is given by

$$(10) \quad 1 + ER_M = \frac{\pi c_1 + (1-\pi)c_2}{z} \\ = \pi\alpha + (1-\pi)\beta.$$

To derive the riskless rate for this case, note that the first-order condition for z simplifies to give

$$(11) \quad \delta\{\pi\alpha^{1-\gamma}z^{-\gamma} + (1-\pi)\beta^{1-\gamma}z^{-\gamma}\} = (W-z)^{-\gamma}.$$

is 0 in state 1 and $\beta z_2 - \alpha z_1$ in state 2, whose value is $(\beta z_2 - \alpha z_1)/\beta$. An increase in the representative consumer's RRA has the effect of lowering both the option's payoff and its value.

Using equation (11), we may now write

$$(12) \quad q_1 + q_2 = \frac{\delta\pi[\alpha z]^{-\gamma}}{[W-z]^{-\gamma}} + \frac{\delta(1-\pi)[\beta z]^{-\gamma}}{[W-z]^{-\gamma}} \\ = \frac{\pi\alpha^{-\gamma} + (1-\pi)\beta^{-\gamma}}{\pi\alpha^{1-\gamma} + (1-\pi)\beta^{1-\gamma}}.$$

The theorem below follows from equation (12).

THEOREM 2: *When production technologies are incomplete, the market risk premium increases as the RRA increases.*

PROOF:

In this case, the expected market return is invariant to the risk aversion. Taking the derivative of (12) gives equation (13), above. The denominator of this expression is positive, and the numerator simplifies to $\pi(1-\pi)\alpha^{-\gamma}\beta^{-\gamma}[\alpha-\beta][\ln(\alpha)-\ln(\beta)]$. This expression is positive, since $\alpha-\beta$ and $\ln(\alpha)-\ln(\beta)$ have the same sign. It thus follows that the numerator increases with γ , which shows that r_f decreases with increasing risk aversion. Since the expected return on the market is fixed [equation (10)], this proves the result.

As the RRA of the representative consumer increases, she will be unable to influence the ratio c_2/c_1 of consumption at the next date. This is the essence of "incompleteness" of production technologies. In order for the markets to clear, the consumer must be satisfied with this risk configuration. This can only happen if the risk premium rises enough to compensate her for the undesired risk. Since the total market return is fixed, this change can be accomplished only with a lower risk-free rate. Another way to see why the risk-free rate

Notes: This table compares equilibrium values when α and β are held constant and RRA is allowed to vary in the complete- and incomplete-markets cases. In the complete-markets case $\alpha = 1.2071$ and $\beta = 6.1118$; in the incomplete-markets case $\alpha = 0.9796$ and $\beta = 1.1520$. These values have been chosen because in both cases they produce an expected market return of 6.58 percent and a risk-free rate of 0.8 percent for RRA = 10, when $\delta = 0.95$. The risk-free rate is invariant to RRA in the complete-markets case, and the expected return on the market is invariant in the incomplete-markets case. The table entries for σ are the standard deviations of the market returns for each case; in the incomplete-markets case, σ is given by the standard deviation of α and β . As shown in the paper, the ratio RP/σ is a constant in the complete-markets case; this is not always obvious in the table, because of rounding error.

falls is to notice that, unlike in the case with complete production markets, the ratio of the maximum quantity of the risk-free asset to total wealth is fixed by technology. If the consumer becomes more risk-averse, the equilibrium price of the risk-free asset must increase, and its return must decrease. Theorem 2 parallels partial-equilibrium results by David P. Baron (1970) for individual firms.⁶

C. Simulating a Linear System

In Table 1, we give some sample simulations for complete- and incomplete-technologies cases. In both systems, α and β have

been chosen so that, with a relative risk aversion of 10 and $\delta = 0.95$, the equilibrium will produce a real risk-free rate of 0.8 percent and an expected return on the market of 6.58 percent.⁷ In the complete markets case, α and β are the simultaneous solution of $1 + r_f = 1/[1/\alpha + 1/\beta] - 1$ and equation (8), for the target values of ER_M and r_f . In the incomplete-markets case, α and β solve equations (10) and (12) simultaneously. For the target values of $ER_M = 6.58$ percent and $r_f = 0.8$ percent, this gives $\alpha = 1.2071$ and $\beta = 6.1118$ in the complete-markets case and $\alpha = 0.9796$ and $\beta = 1.1520$ in the incomplete-markets case. The values of α and β differ for the two cases because in the case of complete production technologies the consumer can achieve the target market return by an allocation of her

⁶Another related result is that of Robert B. Barsky (1989), who shows that in an endowment economy very similar to our incomplete-markets economy, a mean-preserving spread in the risky asset's returns will depress the risk-free rate, although its effect on the market risk premium is ambiguous.

⁷These values are the historic averages in the United States for the period 1898–1978. For details, see Rajnish Mehra and Edward C. Prescott (1985).

production inputs that is skewed toward the low-productivity state. In the case of incomplete production technologies, the achievement of the target is only possible if production efficiency is much more nearly equal in both states.

As proved above, the risk premium is declining in RRA in the complete-markets case and increasing in RRA in the incomplete-markets case.⁸

III. Some Implications of Our Results

A. The Market Return: Risk Ratio

Endowment models of asset pricing typically yield relations in which the market risk premium is proportional to market variance and RRA. For example, Robert Merton (1973) shows that if the risky asset's returns are lognormally distributed and the consumer maximizes an isoelastic utility function, then $(ER_M - r_f)/\sigma_M^2 = RRA$. In the Merton framework, higher RRA results in a higher risk premium, holding variance constant. When the production technologies are endogenized, as in our model with complete production technologies, an entirely different result holds. Under these conditions, the ratio of the market risk premium to the market standard deviation is independent of the relative risk aversion. We prove this result in the following theorem.

THEOREM 3: *In a complete-production-technologies equilibrium with linear production functions, the ratio of the market risk premium to the standard deviation of the market returns is constant.*

PROOF:

For the linear complete-markets case,

$$(14) \quad 1 + r_f = \frac{\alpha\beta}{\alpha + \beta}.$$

⁸The results in Table 1 are to be interpreted as an illustration of the effect of risk aversion on the market risk premium for complete and incomplete markets; for similar calculations see Miles S. Kimball (1988), Benninga and Protopapadakis (1990), and other references cited in the Introduction of this paper.

It follows from equations (8) and (14) that the market risk premium is:

$$(15) \quad RP = \frac{\alpha\beta[\pi X + (1-\pi)Y]}{X\beta + \alpha Y} - \frac{\alpha\beta}{\alpha + \beta} \\ = \frac{\alpha\beta[(1-\pi)\beta - \pi\alpha](Y - X)}{(X\beta + \alpha Y)(\alpha + \beta)}.$$

To compute the standard deviation of the market return, note that the expressions for 1 plus the state-1 and state-2 returns are

$$(16) \quad \frac{\alpha z_1}{z_1 + z_2} = \frac{\alpha\beta X}{\alpha X + \beta Y} \\ \frac{\beta z_2}{z_1 + z_2} = \frac{\alpha\beta Y}{\alpha X + \beta Y}.$$

The standard deviation of the market return, σ_M , can be computed from equation (16):

$$(17) \quad \sigma_M = \frac{\alpha\beta(Y - X)[\pi(1-\pi)]^{1/2}}{\alpha X + \beta Y}.$$

Thus, RP/σ_M is given by

$$(18) \quad \frac{RP}{\sigma_M} = \frac{[(1-\pi)\beta - \pi\alpha]}{(\alpha + \beta)[\pi(1-\pi)]^{1/2}}.$$

This proves the theorem.

Theorem 3 is consistent with one of the results reported by Kenneth R. French et al. (1987). They report better fits when they regress the market risk premium on the standard error rather than on the variance of market returns (see also Merton, 1980; Lillian Ng, 1988). Theorem 3 suggests that a linear regression of the risk premium on the market variance may not be well specified, because the ratio of the risk premium to the variance is itself a function of the RRA, unlike the ratio of the risk premium to the standard error.

B. Nonlinear Production Functions

In Section II, we showed that the risk premium is independent of wealth and falls as the RRA rises, when the production technologies are complete and linear. Since linear technologies imply that the risk-free rate is independent of input choices, when the expected market return falls so does the risk premium. However, when production functions are concave, the risk-free rate depends on production choices. Hence, a change in input choice that leads to lower variability of output will lead to a lower return on the market and also to a lower risk-free rate. If the production technologies are sufficiently concave, the risk-free rate may fall faster than the total market return, so that the risk premium can rise. Since the equilibrium in general will depend on the wealth of the consumer, it follows that the relation between the risk premium and the RRA depends on wealth for complete, concave production technologies.⁹

Some researchers have tested the specification of an isoelastic utility function by testing whether wealth enters significantly in asset pricing equations. This may not be a useful specification test, since the risk premium should be a function of wealth even with isoelastic utility functions, provided there are nonlinearities in production.

IV. Conclusion

General equilibrium macroeconomic models with uncertainty are often cast in the form of microeconomic paradigms of consumer behavior toward risk. We show that this procedure implies some very strong assumptions about the economic environment and that it can lead to misleading conclusions. It is natural to model portfolio choices at the micro level as purely risk-

sharing behavior where risk and return are exogenous to the individual decision-makers. In contrast, macro behavior under uncertainty is primarily about the endogenous choice of aggregate risk and return. In an important sense, macro equilibrium models are about risk-choosing behavior.

In this paper, we demonstrate the importance of this distinction. When the representative consumer is allowed to choose the variability of output, the market risk premium generally declines as the risk aversion of the consumer increases. This happens because a more risk-averse representative consumer will choose lower variability of aggregate output at the expense of lower expected return. However, when the consumer's choice is limited to the pricing of exogenous risk, the market risk premium increases as the risk aversion of the consumer increases, because a more risk-averse consumer requires a higher premium in order to hold willingly the fixed amount of risk.

Finally, the model has interesting implications for the testing of alternative hypotheses about the market return:risk ratio and the relation between the market risk premium and wealth.

The Temporal Stability of Dividends and Stock Prices: Evidence from the Likelihood Function

By DAVID N. DEJONG AND CHARLES H. WHITEMAN*

The debate over whether the expected present value of dividends adequately describes stock prices hinges in part on whether dividends are trend-stationary or integrated processes: it does not if dividends are trend-stationary; it does if they are integrated. This paper argues that classical statistical tests only indicate that there is not sufficient evidence to reject either specification and provides Bayesian analyses designed to reveal the relative support the data give to the two specifications. The analysis suggests that dividends and prices are more likely to be trend-stationary than integrated, leaving the determination of prices a puzzle. (JEL E30, C12, C22)

The temporal stability of dividends and stock prices is an issue central to the recent debate over the validity of the perfect-markets hypotheses (PMH). This hypothesis, sometimes called the efficient- or rational-markets hypothesis, is that stock market returns are not forecastable. If the hypothesis holds, stock prices should equal the present value of expected future dividends. Yet in a widely cited paper in this *Review*, Robert J. Shiller (1981a) assumed that dividends are *trend-stationary* (stationary about a deterministic trend) and found prices to be too volatile to be consistent with the hypothesis. In contrast, the results of Terry A. Marsh and Robert C. Merton (1986) in a subsequent *AER* paper exactly reversed Shiller's, provided that dividends feed back on prices, and are thus *integrated*.

This controversy over the PMH has been intensified by three recent extensions of the

temporal-stability issue. First, the empirical validity of the trend-stationarity assumption has been challenged: dividends and stock prices have been subjected to and have generally passed ever more sophisticated tests for integration. For example, Allan W. Kleidon (1986) drew the inference of integration and concluded that Shiller's results are accounted for by the unit root rather than violations of the PMH. Second, the importance of the trend-stationarity assumption has been downplayed: tests of the PMH which *condition* on integration have been developed. However, while Kleidon's (1986) conditional variance-inequality tests (valid under integration) did not find evidence against the PMH, the cointegration test of John Y. Campbell and Shiller (1987a) rejected restrictions the PMH places on the temporal behavior of prices and dividends when both are integrated. Third, implications of the PMH which hold for both trend-stationary and integrated dividend processes have been investigated.

The import of these extensions hinges on the quality of the evidence concerning the integration of prices and dividends: that of the first two clearly so, and that of the third to the extent that the temporal stability issue remains unresolved. Given the stature of the PMH in economics and finance, it is thus not surprising that enormous efforts have been expended to develop and to apply tests for integration. Substantial progress

Our approach to this problem owes much to the encouragement of John Geweke.

has been made on the asymptotic-distribution theory for ordinary least-squares regression in the presence of unit roots (e.g., Peter C. B. Phillips, 1987, 1988), yet applications have been less than satisfactory. Conflicting evidence is prevalent in the literature, and there seems to be disagreement over what inferences should be drawn.

We study the temporal stability of stock prices and dividends using an alternative procedure based on the likelihood principle; our inferences are *conditional*, given observed data. That is, we ask what the data tell us about the process most likely to have generated the data we observe. In fact, we follow Christopher A. Sims (1988) and Sims and Harald Uhlig (1988) in taking an explicitly Bayesian approach: we summarize sample information in a likelihood function which we feel most researchers would be willing to consider, and we specify prior distributions over exponential and stochastic trends in the time series. The prior distributions we specify render posterior analysis analytically impossible; hence, we follow Teun Kloek and Herman K. van Dijk (1978) and John Geweke (1986, 1988, 1989a,b) in performing necessary integrations by Monte Carlo methods.

Figures 1C–6C depict posterior densities for the dominant autoregressive root (λ ; less than unity if the series is trend-stationary) and the coefficient on the exponential trend (β_4) for several aggregate price and dividend series. The prior used to construct the distributions places substantial weight on the unit root but is uninformative concerning the trend on the indicated domain. The inference we draw is that the series are not integrated: for practically *any* prior that assigns some weight to a positive deterministic trend, the data drive the posterior for the dominant root away from unity and drive the posterior for the deterministic trend away from zero. A very sharp prior on trendless random walks will support the posterior inference of a unit root; this prior is in fact the null hypothesis used in classical tests of the unit-root hypothesis. However, since trend-stationarity is the alternative of interest, with such a sharp prior, why look at the data at all?

Classical procedures have often failed to find evidence against unit roots; this has led some researchers to infer that the stock market data are in fact integrated. Yet similar classical procedures also fail to find evidence against the trend-stationarity assumption (see DeJong et al., 1989a). Aside from inducing the standard tongue-twisting classical result that failure to reject each of two mutually exclusive hypotheses does not settle the issue between them, this pair of findings underscores the importance of considering the *relative* support the competing specifications receive from available evidence. Our Bayesian procedures are designed to do exactly this, and they clearly suggest that, relative to the integration specification, the trend-stationary specification is more likely.

1. Integration, Trend-Stationarity, and the PMH

The debate over the PMH comprises perhaps the best-developed sequence of argument-counterargument in recent empirical economics. To understand the nature of the debate and the contribution of this paper, it will prove useful to review the literature briefly but with some precision.

In support of his assumption of trend-stationarity, Shiller (1981b) tested and rejected the hypothesis of integration for Standard and Poor's (S&P's) dividends over the years 1872–1978. Specifically, using the model

$$(1) \ln(D_t) = \mu + \gamma t + \rho \ln(D_{t-1}) + \varepsilon_t$$

he rejected the integration hypothesis ($\rho = 1$, $\gamma = 0$) using “unit-root” tests developed by Wayne A. Fuller (1976) and David A. Dickey and Fuller (1981); he then proceeded in his (1981a) analysis under the assumption that Dow Jones and S&P's prices and dividends are trend-stationary.

Kleidon (1986) argued that Shiller's (1981a) data are in fact integrated. Using a shorter S&P's data set (1926–1979), Kleidon estimated

$$(2) \ln(X_t) = \delta + \alpha \ln(X_{t-1}) + \xi_t$$

for both prices and dividends and failed to

reject the integration hypothesis ($\alpha = 1$). Further, Kleidon (1986 p. 993) argued that rejections based on (1) are not relevant, since including time as a regressor adds virtually no explanatory power over model (2) and since results derived from (2) are "economically more reasonable" than the results derived from (1).

Kenneth West (1987) and Pierre Perron (1988) argued that unit-root tests based on (2) are inappropriate and misleading when the alternative is trend-stationarity. In short, if $\ln(X_t)$ is trend-stationary, equation (2) is a misspecification: the only way to fit growth in the series in this case is for estimates of α to be driven erroneously to unity, which causes tests based on (2) to be inconsistent. The remedy is to use (1). Perron did so for the S&P's 1871–1984 data using Phillips and Perron's (1988) generalizations of the Dickey and Fuller (1981) tests appropriate when ε_t is serially correlated; he rejected the null for dividends.

Campbell and Shiller (1987b) provided evidence similar to Perron's for the S&P's 1871–1986 data and also tested for integration in dividends and prices using the value-weighted and equally-weighted New York Stock Exchange (NYSE) 1926–1986 data sets. Using the S&P's data, they failed to reject the null for prices but rejected it for dividends; using the NYSE data, they failed to reject the null for both prices and dividends. Alternatively, Campbell and Shiller (1987a) tested for integration in the *levels* of S&P's 1871–1986 prices and dividends. This time they *failed* to reject the null for either prices *or* for dividends.

DeJong et al. (1989a,b) showed that the integration tests employed in these studies, while consistent because the "extraneous" trend is included, can have lower power against plausible trend-stationary alternatives, making nonrejections suspect. DeJong et al. (1989a) also developed a relatively more powerful classical test of the hypothesis $\gamma \neq 0$, $\rho = 0.85$ in (1), which permits serial correlation. They failed to reject the null for the price and dividend series in the Dow, NYSE, or S&P's data sets.

The findings reported above are summarized in Table 1. Results are mixed: there

are three rejections and eight nonrejections of the integration hypothesis, and there are six nonrejections of the trend-stationarity hypothesis evaluated by DeJong et al. (1989a). Inferences concerning integration are evidently fragile, depending upon details of the data used, the time horizon considered, corrections for nuisance parameters, and, we think, the strong priors of researchers. Thus, the status of the debate over Shiller's (1981a) study and Marsh and Merton's (1986) response remains in doubt.

The other extensions have not settled the issue. Kleidon (1986) failed to find evidence against the PMH in the short S&P's data using a conditional volatility test, while Campbell and Shiller (1987a) did find such evidence in the long S&P's data using a cointegration test. Neither approach is valid if the data are trend-stationary. West (1988) tested a volatility relation that is valid under either trend-stationarity or integration and rejected the relation for the 1871–1980 S&P's and the Dow data sets. Yet while the relation West tested is robust to the specification of dividends, the procedure he employed is not: if the dividends West differenced are actually trend-stationary, important parameters used in the construction of the test are estimated inconsistently.¹

Finally, Eugene F. Fama and Kenneth R. French (1988), Andrew W. Lo and A. Craig MacKinlay (1988), and James M. Poterba and Lawrence H. Summers (1988) have developed "variance-ratio" tests which suggest that stock prices exhibit mean-reverting behavior. The evidence in these studies suggests that weekly and monthly returns do revert; hence, the PMH appears suspect. In

¹In a related context, Marjorie A. Flavin (1983) has argued that Shiller's (1981a,b) procedures are plagued by sampling difficulties; thus, even data that satisfy the PMH could appear excessively volatile, though apparently not by the magnitudes detected by Shiller. N. Gregory Mankiw et al. (1985) conducted a test that is, in effect, a hybrid of the West (1988) test and Kleidon's (1986) conditional-variance test. However, they did not report any information concerning the sampling distribution of their test statistic; hence, their results are difficult to interpret.

TABLE 1—EXISTING INTEGRATION AND TREND-STATIONARITY RESULTS

Data	Test	Result	Reference
Standard and Poor's dividends (1871–1978)	equation (1); $H_0: \rho = 1$	H_0 rejected at 5-percent level	Shiller (1981b)
Standard and Poor's dividends and prices (1926–1979)	equation (2); $H_0: \alpha = 1$	cannot reject H_0 at 10-percent level for dividends or prices	Kleidon (1986)
Standard and Poor's dividends and prices (1871–1984)	equation (1); $H_0: \rho = 1$	H_0 rejected at 5-percent level for dividends; not rejected for prices at 10-percent level	Perron (1988)
Standard and Poor's dividends and prices (1871–1986)	equations (1) and (2); H_0 : random walk	cannot reject H_0 at 10-percent level for dividends or prices	Campbell and Shiller (1987a)
Standard and Poor's dividends and prices; levels (1871–1986)	equation (1); $H_0: \gamma = 0, \rho = 1$	H_0 rejected at 5-percent level for dividends; not rejected for prices at 10-percent level	Campbell and Shiller (1987b)
NYSE value- and equally-weighted dividends and prices (1926–1986)	equation (1); $H_0: \gamma = 0, \rho = 1$	cannot reject H_0 at 10-percent level for p or d	Campbell and Shiller (1987b)
Dow, NYSE, and S&P's dividends and prices ¹ (see Appendix for dates)	equation (1); $H_0: \gamma \neq 0, \rho = 0.85$	cannot reject H_0 at 5-percent level for p or d	DeJong et al. (1989a)
Monthly NYSE stock returns (1926–1985)	H_0 : no mean reversion	H_0 rejected	Fama and French (1988)
Weekly NYSE stock returns (1962–1985)	H_0 : no mean reversion	H_0 rejected	Lo and MacKinlay (1988)
Monthly NYSE stock returns (1871–1986)	H_0 : no mean reversion	H_0 rejected	Poterba and Summers (1988)
Annual Dow, NYSE, and S&P's returns (see Appendix for dates)	H_0 : no mean reversion	H_0 not rejected	DeJong and Whiteman (1990)

contrast, DeJong and Whiteman (1990) found no mean reversion in the annual Dow, NYSE, and S&P's price and dividend data sets. Yet so long as the temporal-stability issue remains unresolved, the mean-reversion studies constitute *the* evidence against the PMH.² We now turn to an attempt to settle the issue.

II. Bayesian Inference in a Normal Time-Series Model³

According to the classical metric of sampling distributions, integrated series and trend-stationary series are not dissimilar, and the stock market data are consistent with either hypothesis. Of course, we only

²In a recent paper in this *Review*, Stephen G. Cecchetti et al. (1990) showed that the degree of mean reversion that characterizes stock returns could be well within the margins of sampling error.

³This section makes use of standard Bayesian results (e.g., Arnold Zellner, 1971; Edward E. Leamer, 1978) and also draws heavily on Geweke (1986, 1988, 1989a, b).

have one sample, and given the importance of the temporal-stability issue, it is necessary to draw an inference one way or the other. Classical sampling-theory procedures do not allow such an inference; thus, it is useful to explore other methods of assessing the relative likelihood of the competing specifications.

In specifying the likelihood function that will form the basis for our analysis, we follow common practice and adopt an autoregressive (AR) specification. Denote by y_t the natural logarithm of real dividends (or stock prices). The evolution of y_t is assumed to be described by the autoregression

$$(3) \quad y_t = \beta_0 + \beta(L)y_t + \beta_4 t + \varepsilon_t$$

$$\varepsilon_t \sim \text{i.i.d. } \mathcal{N}(0, \sigma^2)$$

where $\beta(L) = \beta_1 L + \beta_2 L^2 + \beta_3 L^3$; y_0, y_{-1} , and y_{-2} are fixed; and the lag operator L is defined by $L^n y_t = y_{t-n}$.⁴ Three lags were chosen to allow for serial correlation in y_t . Stacking the T observations in the standard fashion, we have $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$.⁵ We define

$$(4) \quad \lambda(z) \equiv 1 - \beta(z) = \prod_{j=1}^3 (1 - \lambda_j z).$$

The roots of the AR representation of $\{y_t\}$ correspond to the p factors of $\lambda(z)$ or, equivalently, the roots of $F^p \lambda(F)$, where $F = z^{-1}$. We denote these roots by $\lambda_1, \lambda_2, \dots, \lambda_p$ and define the dominant autoregressive root by $\Lambda = \max_j |\lambda_j|$. Trend-stationarity corresponds to $\Lambda < 1$; integration (or difference-stationarity) is the special case $\Lambda = 1$. A formulation that makes

trend-stationarity the special case is considered in Section IV.

Sample information is summarized in the likelihood function

$$\ell(\boldsymbol{\theta}|\mathbf{y}, \mathbf{X}) = (2\pi\sigma^2)^{-T/2} \times \exp\left[-(1/2\sigma^2)(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})\right].$$

The classicist views the likelihood function as the sampling distribution for the data $\{\mathbf{y}, \mathbf{X}\}$ given a fixed value of $\boldsymbol{\theta} \equiv (\boldsymbol{\beta}', \sigma^2)$. Alternatively, the Bayesian views the likelihood function as an ingredient in the computation of the conditional probability density for $\boldsymbol{\theta}$ given $\{\mathbf{y}, \mathbf{X}\}$. In particular, with prior views about $\boldsymbol{\theta}$ summarized in the density $p(\boldsymbol{\theta})$, the posterior density for $\boldsymbol{\theta}$ is

$$P(\boldsymbol{\theta}|\mathbf{y}, \mathbf{X}) = \ell(\boldsymbol{\theta}|\mathbf{y}, \mathbf{X})p(\boldsymbol{\theta})/f(\mathbf{y}, \mathbf{X})$$

$$\propto \ell(\boldsymbol{\theta}|\mathbf{y}, \mathbf{X})p(\boldsymbol{\theta})$$

where $f(\mathbf{y}, \mathbf{X})$ is a constant from the point of view of the $\boldsymbol{\theta}$ distribution.

The prior distribution we posit is the typical noninformative one: flat over the β_j and $\ln(\sigma)$ (i.e., $p(\boldsymbol{\theta}) = \sigma^{-1}$). Conditioned on σ , the posterior distribution for $\boldsymbol{\beta}$ is normal with mean \mathbf{b} and covariance matrix $\sigma^2(\mathbf{X}'\mathbf{X})^{-1}$. The marginal density for σ , $P(\sigma|\mathbf{y}, \mathbf{X})$, is inverted gamma: $\sigma^2 = \nu s^2/u$, where u is distributed as χ^2 with ν degrees of freedom.

In practice, the prior we employed was given by $\pi(\boldsymbol{\theta}) = p(\boldsymbol{\theta})\iota_A(\boldsymbol{\theta})$, where $\iota_A(\boldsymbol{\theta})$ is the indicator function for the event A . For example, one such A is given by

$$A = \{(\beta_4, \Lambda): 0 \leq \beta_4 \leq 0.016, 0.55 \leq \Lambda \leq 1.055\}.$$

If $g(\boldsymbol{\theta})$ is any function of interest [e.g., $g(\boldsymbol{\theta}) = (\Lambda, \beta_4)$], then

$$E[g(\boldsymbol{\theta})|A, \mathbf{y}, \mathbf{X}]$$

$$= \frac{\int_{\boldsymbol{\theta} \in A} g(\boldsymbol{\theta}) \ell(\boldsymbol{\theta}|\mathbf{y}, \mathbf{X}) p(\boldsymbol{\theta}) d\boldsymbol{\theta}}{\int_{\boldsymbol{\theta} \in A} \ell(\boldsymbol{\theta}|\mathbf{y}, \mathbf{X}) p(\boldsymbol{\theta}) d\boldsymbol{\theta}}$$

⁴A referee points out that the homoscedasticity assumption concerning ε_t in (3) might usefully be relaxed. Doing so would forfeit comparability with the classical unit-root tests discussed above and lies beyond the scope of this paper. Further, Geweke (1989a) seems to indicate that relatively little is gained (for IBM prices) by admitting ARCH. Still, such an extension is part of planned future work.

⁵Specifically, $\mathbf{y} = (y_1 \dots y_T)'$, $\mathbf{X} = (\mathbf{x}_1' \dots \mathbf{x}_T')'$ with $\mathbf{x}_t = (1 \ y_{t-1} \ y_{t-2} \ y_{t-3} \ t)'$, and $\boldsymbol{\beta} = (\beta_0 \ \beta_1 \ \beta_2 \ \beta_3 \ \beta_4)'$.

TABLE 2—ROOT CALCULATIONS, TREND EXCLUDED

Series	μ_Λ	σ_Λ	$p(\Lambda \geq 0.975 \beta_4 = 0)$	$p(0.65 \leq \Lambda < 1.16 \beta_4 = 0)$
Dow Jones dividends	0.916	0.071	0.190	0.992
Dow Jones prices	0.898	0.082	0.159	0.980
NYSE dividends	0.984	0.031	0.645	1.000
NYSE prices	0.971	0.037	0.473	1.000
Standard and Poor's dividends	0.953	0.032	0.235	1.000
Standard and Poor's prices	0.951	0.031	0.217	1.000

Notes: μ_Λ denotes the posterior mean of the dominant root computed from the AR(3) representation of the series (with trend excluded), and σ_Λ denotes the posterior variance. These results are based on 20,000 replications.

TABLE 3—ROOT CALCULATIONS, TREND INCLUDED

Series	μ_Λ	σ_Λ	μ_{β_4}	σ_{β_4}	ρ_{Λ, β_4}	$p(\Lambda \geq 0.975 A)$	$p(\beta_4 \leq 0.001 A)$	$p(A)$
Dow Jones dividends	0.717	0.096	0.006	0.003	-0.504	0.004	0.018	0.872

Standard and Poor's dividends	0.719	0.091	0.003	0.001	-0.657	0.000	0.023	0.911
Standard and Poor's prices	0.869	0.065	0.002	0.001	-0.686	0.015	0.241	0.961

Notes: μ_Λ and σ_Λ are as described in Table 2, and μ_{β_4} and σ_{β_4} are analogous for the posterior exponential trend of the series; ρ_{Λ, β_4} is the posterior correlation between the trend coefficient and dominant root. These results are based on 20,000 replications. The event A is $\{0 \leq \beta_4 \leq 0.016, 0.55 \leq \Lambda \leq 1.055\}$.

and

$$PR[\theta \in A | y, X] = \frac{\int_{\theta \in A} \ell(\theta | y, X) p(\theta) d\theta}{\int_{\theta} \ell(\theta | y, X) d\theta}.$$

The integrals cannot be evaluated analytically, but integration by Monte Carlo (Kloek and van Dijk, 1978; Geweke, 1986, 1988, 1989a, b) is straightforward. That is, given a sequence of independent drawings of random variables from the posterior distribution $P(\theta | y, X)$, we can estimate these integrals by averaging across drawings.⁶ Geweke

(1989b) shows that these sample averages are consistent estimators of the integrals themselves (in Monte Carlo replications). Moreover, in computing the probabilities of various events, we follow Geweke (1989b) and note that each drawing can be considered a Bernoulli trial with success probability q . The natural estimate of q is the number of successes divided by the number of trials, and the standard error of this estimate is $[q(1-q)/n]^{1/2}$. Thus, the standard error of the estimate of q after $n = 10,000$ is no greater than 0.005.

In the next section, we present numerical estimates of the joint densities, $P(\Lambda, \beta_4 | y, X)$, and use them to draw inferences concerning difference- versus trend-stationarity. We infer that the integration representation is not implausible if there is

⁶Details of this procedure are spelled out in Geweke (1989b) and DeJong and Whiteman (1991).

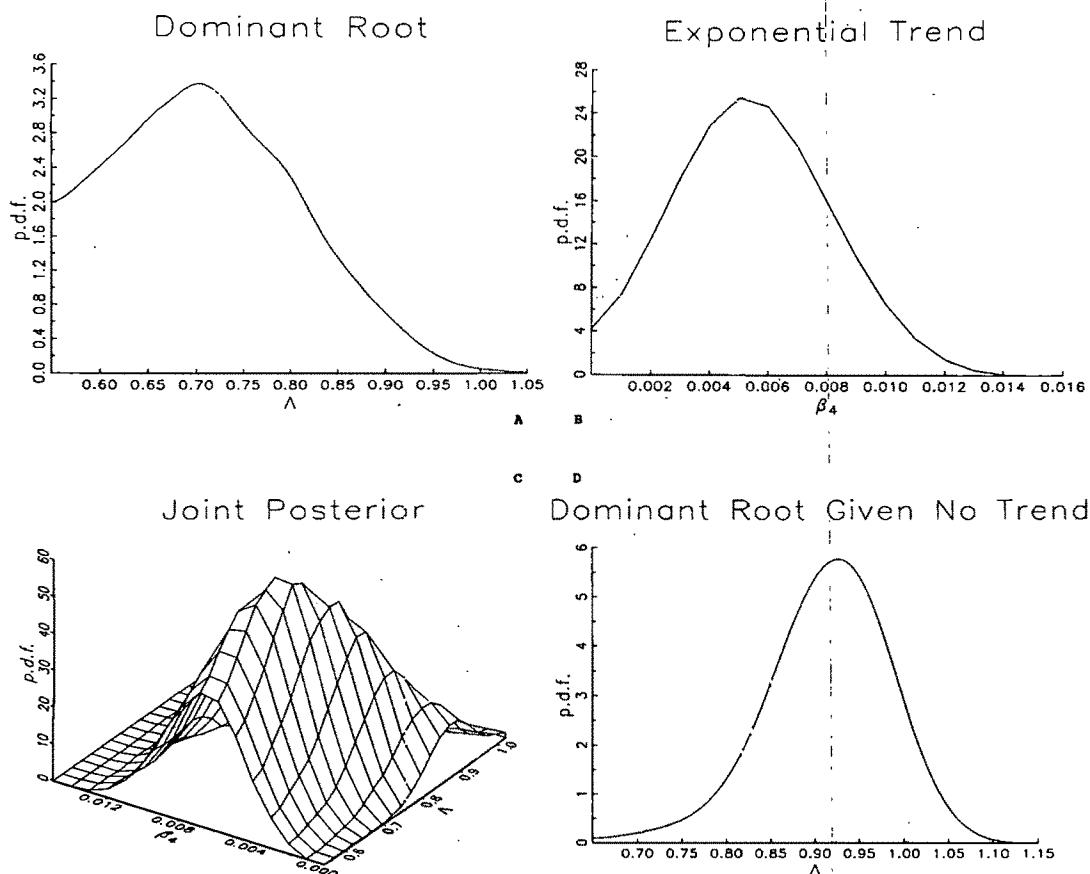

FIGURE 1. DOW JONES DIVIDENDS 1928-1973

at least a 5-percent posterior probability that Λ exceeds 0.975.

III. Inference Concerning Exponential Trend and the Dominant Root

We conduct posterior inference for aggregate annual dividends and stock prices from the Dow, the NYSE, and S&P's indexes (the data are described in the Appendix). We consider two priors; we first restrict $\beta_4 = 0$ and then view β_4 as uniform on $[0, 0.015]$. The associated posterior distributions for the exponential trend (β_4) and dominant AR root (Λ) are summarized in Tables 2 and 3 and in Figures 1-6.⁷

⁷The posteriors were calculated as follows. A 101×16 grid was created over $\{(\Lambda, \beta_4) \in [0.55, 1.05] \times$

In each figure, panel A presents the marginal posterior probability density function (p.d.f.) for Λ , panel B presents the marginal density for β_4 , panel C presents the joint (Λ, β_4) posterior, and panel D presents the density for Λ obtained using the zero-trend prior. The densities represent the combination of the raw histograms with a locally quadratic smoothness prior.⁸

$[0, 0.015])$. For each of 20,000 replications, (Λ, β_4) was calculated, and posterior frequencies were accumulated in the 1,616 bins (of width 0.005 in the Λ -dimension and 0.001 in the β_4 -dimension).

⁸The smoothness priors are akin to those used by Shiller (1973) in estimating distributed lags, and they have a "mixed estimation" interpretation (Henri Theil and A. H. Goldberger, 1961). Let \mathbf{h} be a 101×1 vector containing raw histogram values, and let \mathbf{D} be a $101 \times$

FIGURE 2. DOW JONES PRICES 1928-1978

The first finding of interest is that the price and dividend series do not give rise to very different posteriors. With either of the two trend priors, the price and dividend posteriors are similarly shaped and located.

The posteriors of Λ obtained under the zero-trend prior strongly support integration; the posterior means range from 0.898

(for Dow dividends) to 0.971 (for NYSE prices) and are each within 1.65 standard deviations of unity. Further, the posterior probability that Λ exceeds 0.975 is no less than 15 percent. This result corresponds to Kleidon's (1986) finding that, when the deterministic trend alternative is excluded from the analysis, the integration representation is supported.

When we relax the zero-trend prior, the posterior modes of the exponential trends (Figs. 1B-6B) always exceed zero. For the S&P series, the trend is small, but the posterior density suggests a value of 0.001 or 0.002. Under this prior, the integration hypothesis is not supported; the posterior means for Λ range from 0.717 (standard deviation = 0.096) in the Dow dividends se-

101 matrix with first row $(-1 \ 1 \ 0 \ \dots \ 0)$, second row $(1 \ -2 \ 1 \ 0 \ \dots \ 0)$, third row $(0 \ 1 \ -2 \ 1 \ 0 \ \dots \ 0)$, ..., 100th row $(0 \ \dots \ 0 \ 1 \ -2 \ 1)$, and last row $(0 \ \dots \ 0 \ 1 \ -1)$. Note that Dh is a vector of second differences of the histogram values (end points excepted). The prior is that $Dh \sim \mathcal{N}(0, \kappa^2)$. Let $Z = [ID'/\kappa]$. The smoothed density is given by $h^* = (Z'Z)^{-1}Z'h$. The figures use $\kappa = 10$.

FIGURE 3. NYSE DIVIDENDS 1926-1981

ries to 0.869 (SD = 0.065) in the S&P price series. Further, the root distributions are skewed left; hence, the upper 1.65σ bound never exceeds unity. Moreover, given the restriction to Λ (minimum probability 0.87), the estimated probability that Λ is greater than 0.975 never exceeds 3.2 percent.

One of the most striking results is the strong negative correlation between Λ and β_4 . This correlation ranges from -0.504 (Dow dividends) to -0.753 (NYSE dividends), and it is clear that restricting the exponential trend to zero (an inference wildly at variance with the data, having posterior probability greater than 0.033 in only one case [S&P prices], when it reaches 0.24) produces estimates of Λ that are far too

large. Hence, while in Table 2 and Figures 1D-6D it appears that unit roots pervade the stock price and dividend series, this is an artifact of the unsupported restriction $\beta_4 = 0$; when the trend is unrestricted, the dominant roots appear to be about 0.8.

The figures suggest the following inference: with no apparent particular initial feeling concerning the trend and dominant root, one would be moved by the data toward the trend-stationary specification. Yet while the prior we consider is flat over the parameters β , and in particular the trend coefficient β_4 , it is *not* flat over Λ , which represents a nonlinear transformation of these parameters. Figure 7A illustrates the shape of our prior over Λ , which was calcu-

FIGURE 4. NYSE PRICES 1926-1981

lated by the Monte Carlo method described above, except that the drawings of β were obtained from a uniform distribution.⁹ Note that increasingly large values of Λ receive increasing prior weight. This is a "Marsh-Merton" prior: integration is relatively supported over trend-stationarity. Despite this support, the posteriors we obtain clearly favor the inference of trend-stationarity. Recalculating the posteriors under a flat prior over dominant roots would involve

downweighting large roots and increasing weights on small roots; the posteriors would shift leftward, and unit roots would look even less plausible.

IV. Extensions

In any statistical analysis, results can be sensitive to (i) the researcher's prior views and (ii) specification of the likelihood function. To investigate the robustness of our results to the prior, we consider the *coherence* of our procedure: what prior ensures against the trend-stationarity inference in repeated samples from difference-stationary processes? To examine the robustness to the specification of the likelihood function,

⁹The reason we calculate our "prior" over Λ is that it is a very complicated nonlinear transformation of β : roots of a polynomial are calculated, an absolute value is taken, and to top things off, a maximum is taken.

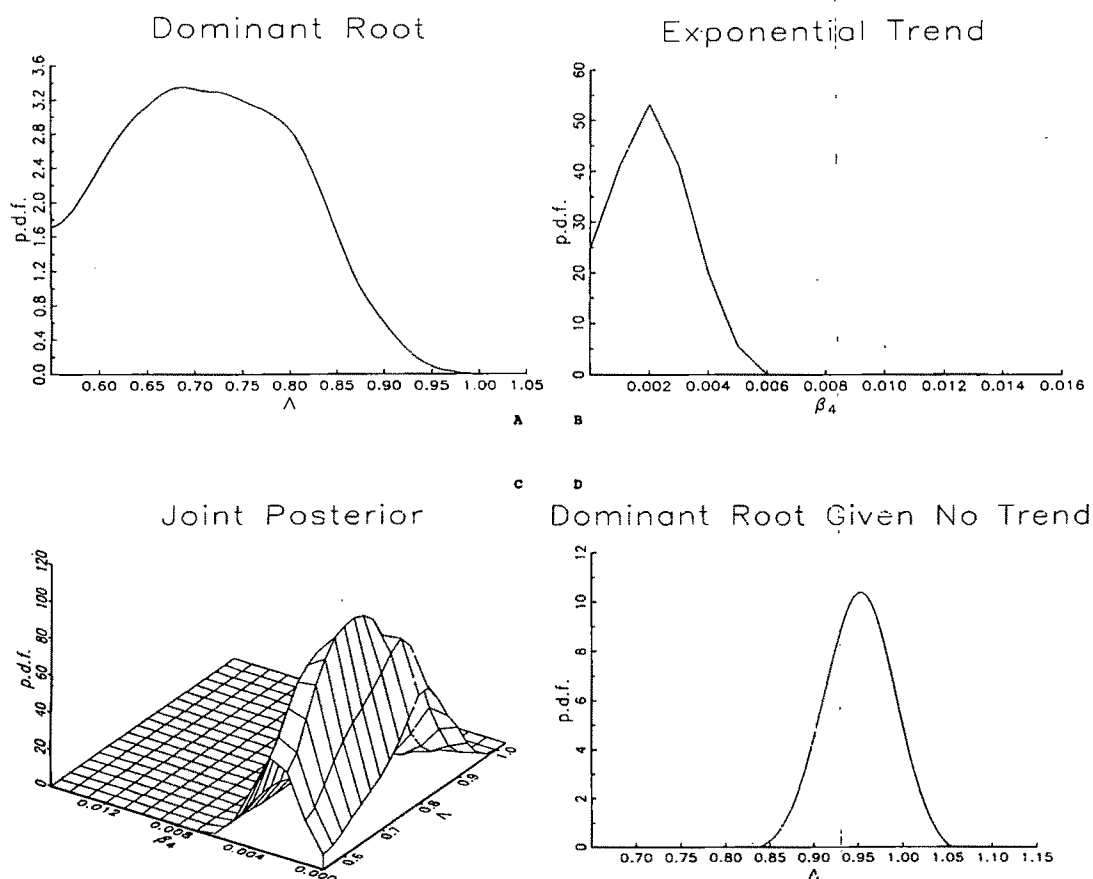

FIGURE 5. STANDARD AND POOR'S DIVIDENDS 1871-1985

we consider an unobserved-stochastic-trend generalization of (3).

A. Robustness to Prior

The coherence issue was investigated following DeJong and Whiteman (1991), in which we developed a prior distribution over (Λ, β_4) which insures that our inferential procedure errs no more than 5 percent of the time in repeated samples when the series under consideration is of length 100 and follows a random walk with drift and unit innovation variance. The prior over Λ is the same as that pictured in Figure 7A, but assigns decreasing weight to increasingly large trend coefficients. Specifically, the prior over β_4 is a beta distribution propor-

tional to

$$(1 - \beta_4)^{(B-1)} \quad \beta_4 \in [0, 0.015]$$

with $B = 6$; this "5-percent prior" is illustrated in Figures 7B-D. Reweighting our original posteriors using the 5-percent prior, we find that the integration representation continues to appear implausible for each series except NYSE prices; the posterior probability that Λ exceeds 0.975 is 6.1 percent in this case (see Table 4 for details).

B. Robustness to Specification

While the approaches taken by classical unit-root testers do suggest substantial agreement over the form of the likelihood

FIGURE 6. STANDARD AND POOR'S PRICES 1871-1985

function, the unit root remains a special case in these (and our) formulations. Thus, to investigate the sensitivity of our results to the likelihood function utilized above, we consider a generalization that makes trend-stationarity the special case. In particular, we consider an unobserved components model for y_t of the form

$$(5) \quad y_t = \gamma + \mu_t + \Psi_t$$

where

$$(6) \quad \mu_t = \delta + \mu_{t-1} + \eta_t$$

$$\eta_t \sim \text{i.i.d.} \mathcal{N}(0, \sigma_\eta^2)$$

$$(7) \quad \Psi_t = \phi_1 \Psi_{t-1} + \phi_2 \Psi_{t-2} + \phi_3 \Psi_{t-3} + \varepsilon_t$$

$$\varepsilon_t \sim \text{i.i.d.} \mathcal{N}(0, \sigma_\varepsilon^2)$$

and $\{\eta_t\}$ and $\{\varepsilon_t\}$ are independent. Notice that if $\sigma_\eta^2 = 0$, then $\mu_t = \mu_0 + \delta t$, and y_t has the AR(3) representation given in (3). When $\sigma_\eta^2 > 0$, y_t possesses a stochastic trend and can be represented as ARIMA(3,1,3):

$$(8) \quad \Delta y_t = \delta + \phi(L)^{-1} \theta(L) \varepsilon_t$$

where $\theta(L) = 1 + \theta_1 L + \theta_2 L^2 + \theta_3 L^3$, $\{\varepsilon_t\}$ is the one-step-ahead forecast error in predicting $\{y_t\}$ linearly from its own past, and using the notational convention $|f(z)|^2 = f(z)f(z^{-1})$,

$$(9) \quad |\theta(z)|^2 \sigma_\varepsilon^2 = |\phi(z)|^2 \sigma_\eta^2 + |1 - z|^2 \sigma_\varepsilon^2.$$

We denote the dominant moving-average root by $\lambda = 1/\max_z |\arg[\theta(z) = 0]|$.

FIGURE 7. PRIOR DISTRIBUTIONS

Expression (9) indicates the factorization problem that must be solved to determine $\theta_1, \theta_2, \theta_3$, and σ_e^2 from the parameters $\phi_1, \phi_2, \phi_3, \sigma_\eta^2$, and σ_ε^2 of (5). Note that when $\sigma_\eta = 0$, the MA representation for Δy_t has a zero at unity. Thus, there are *two* senses in which trend-stationarity is the special case in this formulation: $\sigma_\eta = 0$ and $\lambda = 1$.

Define $\Theta = (\phi_1 \phi_2 \phi_3 \sigma_\eta \sigma_\varepsilon)$, stack the deviations from the mean of the T observations $\Delta y_1, \dots, \Delta y_T$ in the $T \times 1$ vector y , and write $Eyy' = \sigma_e^2 V$. The likelihood function of y under this specification is given by

$$\log \mathcal{L}(\Theta | y) = -(T/2) \log 2\pi - (T/2) \log \sigma_e^2 - \frac{1}{2} \log |V| - \frac{1}{2} \sigma_e^2 y' V^{-1} y.$$

Posterior analysis was conducted by combining $\mathcal{L}(y | \Theta)$ with an uninformative prior over Θ .¹⁰

We focused on three parameters in our analysis: the dominant AR root λ , the dominant MA root λ , and the ratio of the standard deviation of the stochastic-trend innovation to the total standard deviation of the series, $\sigma_\eta / \sigma_\varepsilon$. The prior and posterior distributions for these parameters were ob-

¹⁰The prior was

$$\pi(\beta) \propto \begin{cases} \sigma_e^{-1} & \forall \Theta \text{ such that } \lambda \in [0.5, 1], \\ & \lambda \in [0.55, 1.05], \sigma_\eta \geq 0, \sigma_\varepsilon \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

Notes: The 5-percent prior ensures that our decision rule errs no more than 5 percent of the time in repeated samples from a random walk with drift and unit innovation variance. The decision rule was: draw the unit-root inference if there is at least 5-percent posterior probability on dominant roots exceeding 0.975. Asterisks denote situations in which the unit-root inference is *not* implausible. For the unobserved-components model, $\sigma_\eta / \sigma_\epsilon$ is the ratio of standard deviations of the stochastic-trend innovation to the total innovation in the series estimated from (5), λ denotes the dominant root of the MA component estimated in the model, and Λ denotes the dominant root of the AR component estimated in the model. Posterior standard deviations are given in parentheses.

tained using the numerical integration methods described above.¹¹ A complication in generating posteriors in this case is that it is not possible to generate drawings of Θ directly from the posterior distribution $p(\Theta|y)$; this problem was sidestepped using the importance-sampling techniques described by Geweke (1989b) (see DeJong and Whiteman [1989] for details).

The results obtained using the unobserved-components model are summarized in Table 4 and Figure 8. Consider first the posterior distributions of Λ . While the prior over Λ is the same as in the AR(3) case, the posteriors are rightshifted relative to the AR(3) distributions. In particular, the posterior probability that Λ exceeds 0.975 is greater than 5 percent for two series under this specification: Dow prices (0.179) and NYSE prices (0.095). Under our inferential procedure, we conclude that the integration

representation does not appear implausible for these series in this case; however, the posteriors continue to suggest that the *most likely* values for Λ are less than unity. The integration representation continues to appear implausible for the remaining series.

Consider now the results obtained for $\sigma_\eta / \sigma_\epsilon$. While the prior provides considerable support for the significance of the stochastic trend (the prior mode of $\sigma_\eta / \sigma_\epsilon$ is approximately 0.4), the posteriors provide much weaker support. In fact, the posterior mode of $\sigma_\eta / \sigma_\epsilon$ exceeds 0.1 in only the Dow and NYSE price series, where the posterior modes are 0.19 and 0.12. Moreover, the posterior distributions of λ have a mode of unity for each series and are concentrated much more tightly near unity than is the prior over λ . Since the MA representation of Δy_t has a zero at unity when σ_η is small, this suggests that if there are stochastic-trend components in these series, they are small.

To summarize, using the AR(3) likelihood function, integration looked quite implausible; with the unobserved-components ARIMA(3, 1, 3) specification, integration continues to look implausible, but perhaps

¹¹The unobserved components formulation adds to the complexity of the prior; again, we computed the implications that flat priors over the ϕ 's carry for parameters of interest, λ and Λ .

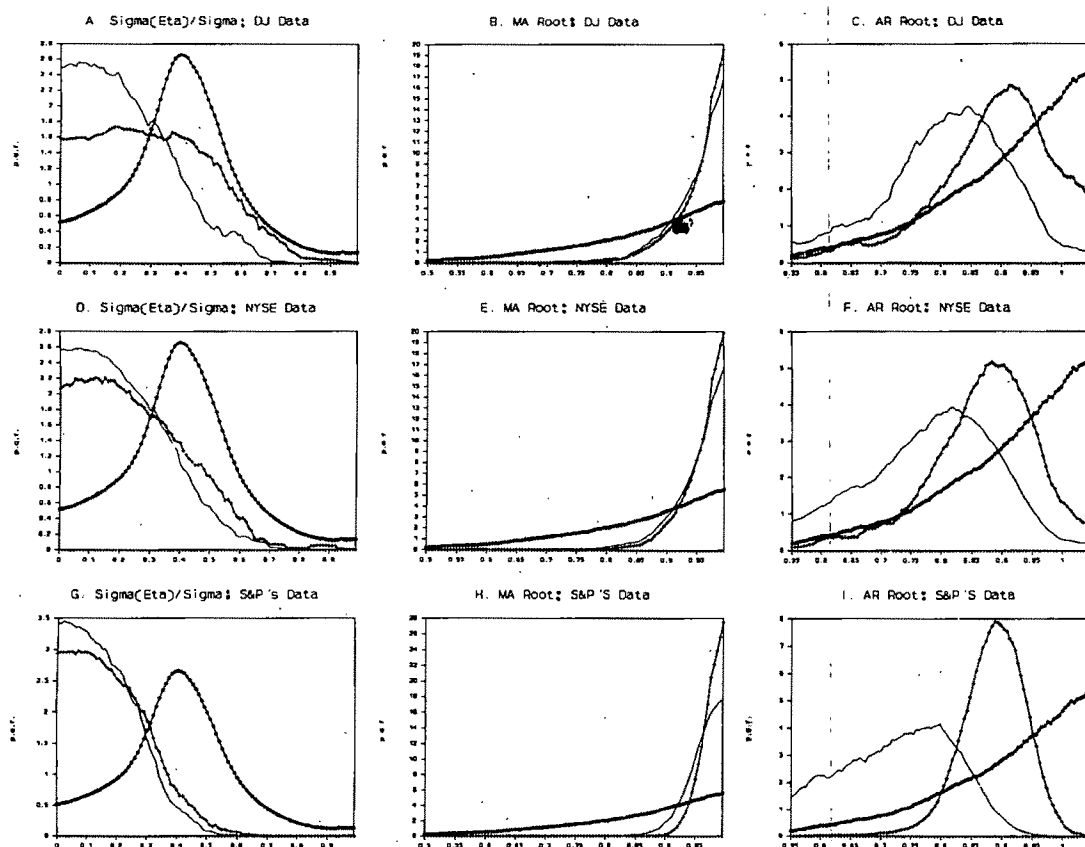

FIGURE 8. UNOBSERVED-COMPONENTS MODEL: — = DIVIDENDS; + = PRICES; ◇ = PRIOR

less strikingly so. That there is some sensitivity to specification is a result not unlike those of John H. Cochrane (1988) and Lawrence J. Christiano and Martin Eichenbaum (1989). Yet the unobserved-components priors we used were quite sharp in favor of integration: the dominant AR root prior peaks at unity, and the prior mode for the stochastic trend innovation is distinctly positive. Despite these prior views in favor of integration, the data drive one away from this, toward trend-stationarity. *Very* strong prior views in favor of integration may not be shaken, but Figure 8 suggests that moderately strong ones would be.

V. Concluding Remarks

The results in this paper seem to encompass existing integration results. When the

exponential trend is restricted to zero, our Figures 1D–6D and Table 2 suggest that the dividend and stock price series are integrated. This corresponds to Kleidon's (1986) results (and his "prior" concerning the presence of trends). But on either classical or Bayesian grounds, the zero-trend restriction is erroneous: Classical unit-root tests which exclude deterministic trends are inconsistent against trend-stationary alternatives, and our posterior distributions suggest that the zero-trend restriction is inappropriate. When the trend coefficient is not restricted, classical unit-root tests do not reject the null (but have low power), classical trend-stationarity tests do not reject the null (and have moderate power), and our posteriors suggest that trend-stationarity is strongly supported. Moreover, upon differencing the series, we find evidence of unit

dominant moving-average roots, suggesting that differencing one time is too many.

This of course is the real issue: how does one handle trends in the data? The series may grow because they are deterministically trended or because they are drifting random walks. Using a classical unit-root test, one examines whether there is evidence *against* the drifting random walk. If one takes the opposing view, adopting trend-stationarity as the null hypothesis, classical tests examine whether there is evidence *against* trend-stationarity. The classical story ends here: neither test rejects, and hence one is left with insufficient evidence to discard either of two mutually exclusive hypotheses. To settle the issue, it is necessary to know which of the two competing specifications is more likely. The Bayesian procedures we adopted enable us to discover this; for the real stock price and dividend series, the trend-stationary specification seems more plausible than the integration specification. Thus, the appropriate inference, we think, is that deterministic exponential trends pervade the data, and dominant roots are less than unity. Thus, Shiller's (1981a) exponential detrending of the data seems justified, and the perfect-markets puzzle remains, unexplained by the integration of dividends.

APPENDIX

A. Data Set 1: Modified Dow Jones Industrial Average (Annual 1928–1978)

Here, P_t and D_t refer to the real price and dividends of the portfolio of 30 stocks comprising the sample for the Dow Jones Industrial Average when it was created in 1928. However, due to the fact that adjustments are continually made to the stocks used to calculate this average, Shiller has extensively modified it to control for these adjustments. These modifications are described in the appendix of his 1981a paper. Source: Robert Shiller.

B. Data Set 2: Value-Weighted NYSE Index (Annual 1926–1981)

P_t represents the January value-weighted NYSE stock price divided by the January

producer price index (PPI). D_t represents total dividends for the year accruing to the portfolio represented by the stocks in the index, divided by the annual average PPI. In the Marsh and Merton (1987) analysis, P_t represents December rather than January prices, but January prices are considered here to remain consistent with the Shiller dating scheme. Source: Center for Research in Security Prices (CRSP; University of Chicago) data set.

C. Data Set 3: Modified Standard and Poor's Series (Annual 1871–1985)

The price series $\{P_t\}$ is Standard and Poor's monthly composite stock price index for January, divided by the producer price index (January PPI starting in 1900, annual average PPI before 1990 scaled to 1.00 in the base year 1979). The dividend series $\{D_t\}$ represents the total dividends for the calendar year accruing to the portfolio represented by the stocks in the index, divided by the average PPI for the year. These data differ slightly from Shiller's (1981a) numbers; some adjustments have been made to correct minor errors in the original data, and the series have been updated to 1985. A Note on Optimal Fines When Wealth Varies Among Individuals

By A. MITCHELL POLINSKY AND STEVEN SHAVELL*

An important result in the economic theory of enforcement is that, under certain circumstances, it is optimal to impose the highest possible fine—equal to an individual's entire wealth—with a relatively low probability of detection. The reasoning supporting this conclusion, which is usually attributed to Gary S. Becker (1968), is well known: if the fine is not at its highest level, enforcement costs can be reduced without affecting deterrence. This can be done by raising the fine to its highest level and lowering the probability of detection proportionally, so that the expected fine—and thus deterrence—is unchanged. Hence, according to this argument, it cannot be optimal for the fine to be less than an individual's wealth.

It is puzzling, of course, that this result differs so much from reality. Fines equal to an individual's wealth hardly ever are imposed. Several explanations have been offered to reconcile Becker's theory with this fact. For example, it has been shown that, if individuals are risk-averse, fines less than their wealth generally are optimal; and it has been argued that it is inequitable to impose fines greatly exceeding the harm done.¹ This note provides a new explanation of why fines are limited.

*Stanford Law School, Stanford, CA 94305, and Harvard Law School, Cambridge, MA 02138, respectively. Both authors also are research associates of the National Bureau of Economic Research. Polinsky's research was supported by the John M. Olin Program in Law and Economics at Stanford Law School. Shavell's research was supported by the National Science Foundation (grant SES-8821400). Helpful comments were provided by Louis Kaplow and two anonymous referees.

¹In a previous article (Polinsky and Shavell, 1979), we develop the risk-aversion explanation, and R. A. Carr-Hill and N. H. Stern (1979 pp. 281–95) discuss the equity explanation (as well as several others). In addition, George J. Stigler (1970) proposes an explana-

We will demonstrate that, if the wealth of individuals varies, as is obviously realistic, the optimal fine is less than the wealth of the highest-wealth individuals and may be less than the wealth of most individuals. In other words, the optimal fine is such that only relatively low-wealth individuals pay everything they have; all other individuals pay the fine, which is less than their wealth.

To understand our conclusion, consider why the argument associated with Becker cannot be applied when wealth varies. Suppose that the fine is less than the wealth of the highest-wealth individuals. If the fine is raised and the probability of detection is lowered proportionally, it is true that those who can pay the higher fine are deterred to the same extent. However, those who cannot pay the higher fine are deterred less. As a consequence, it generally is not optimal to raise the fine to the highest possible level.

For example, a fine of \$100 for speeding may be optimal because many drivers may have so little in savings that it would be difficult to collect more from them. If a much larger fine were imposed with a much smaller probability, these drivers would be inadequately deterred. Thus, a fine of \$100 may be optimal, which would mean that all speeding drivers with wealth exceeding \$100 would pay a fine that is less than their wealth.

I. Analysis and Example

In the model, risk-neutral individuals contemplate whether to commit a harmful act. Each individual is identified by the ben-

tion based on marginal deterrence, and Shavell (1991) presents an explanation based on the assumption that the probability of detection is the same for different types of harm. See also Richard A. Posner (1986 pp. 205–12).

efit he would obtain from committing the act and by his level of wealth. If an individual commits the harmful act, he will be made to pay a fine with some probability; this probability is determined by the enforcement expenditures of the state.

The following notation will be used:

- h = harm caused if the harmful act is committed ($h > 0$);
- b = benefit from committing the harmful act ($b \geq 0$);
- $r(b)$ = probability density of b ($r > 0$ for all $b \geq 0$);
- w = wealth of an individual ($w \geq 0$);
- $s(w)$ = probability density of w ($s > 0$ for all $w \geq 0$);
- $f(w)$ = fine for committing the harmful act for an individual whose wealth is w ($0 \leq f(w) \leq w$);²
- c = enforcement costs of the state ($c \geq 0$);
- $p(c)$ = probability of detection ($p'(c) > 0$, $p''(c) < 0$).

The probability of detection is assumed to be the same for individuals of different wealth. This assumption is crucial, as will be commented upon below. Also, the distribution of benefits is assumed to be the same for different levels of wealth; this assumption is not essential.

Social welfare is the sum of the benefits obtained by individuals who commit the harmful act, less the harm done and less enforcement costs. To determine social welfare, observe that an individual will commit the harmful act if and only if³

$$(1) \quad b \geq pf(w).$$

Hence, social welfare is

$$(2) \quad \int_0^\infty \int_{pf(w)}^\infty (b - h)r(b) db s(w) dw - c.$$

²Implicit in the assumption that $f(w) \leq w$ is the further assumption that an individual's wealth does not include the benefit he obtains from committing the harmful act. The latter assumption is made only for convenience.

³The assumption that an individual commits the act when $b = pf(w)$ is immaterial.

Let us first determine the optimal fine, $f^*(w)$, assuming that the probability of detection, p , is positive. Clearly, given p and any w , $f^*(w)$ is the f that maximizes

$$(3) \quad \int_{pf}^\infty (b - h)r(b) db.$$

The derivative of (3) with respect to f is $p(h - pf)r(pf)$, which is positive for $f < h/p$, 0 at $f = h/p$, and negative for higher f . Thus, the optimal f equals h/p if h/p is feasible, that is, if $h/p \leq w$; otherwise, the optimal f is w . In other words, $f^*(w) = \min(h/p, w)$.

This result can be restated as follows. *The optimal fine equals an individual's wealth for every individual with wealth less than h/p ; for all other individuals, who have higher wealth, the optimal fine is h/p , which is less than their wealth.* Equivalently, the optimal fine is h/p for everyone, but those who cannot pay this amount pay what they can. Note that those who can pay h/p are optimally deterred (i.e., act in the first-best manner) since their expected fine equals the harm caused.⁴

Next consider the optimal probability of detection. Because $f^*(w) = \min(h/p, w)$, (2) can be rewritten as

$$(4) \quad \int_0^{h/p} \int_{pw}^\infty (b - h)r(b) db s(w) dw + \int_{h/p}^\infty \int_h^\infty (b - h)r(b) db s(w) dw - c.$$

The first term relates to individuals who pay their wealth w when fined because they cannot pay h/p ; the second term relates to individuals who have wealth of at least h/p

⁴In Polinsky and Shavell (1984 pp. 96–7), we briefly considered optimal fines when there are two types of individuals who differ in terms of wealth. It was shown there that the optimal fine for an individual in the low-wealth group is equal to his wealth and that the optimal fine for an individual in the high-wealth group is larger but not necessarily equal to his wealth. The analysis here generalizes that result and is consistent with it.

and who therefore pay h/p and are optimally deterred.

Setting the derivative of (4) with respect to c equal to zero gives the relevant first-order condition,

$$(5) \int_0^{h/p} p'(c)(h - pw)wr(pw)s(w)dw = 1.$$

The left-hand side is the marginal benefit of raising c : some individuals with wealth less than h/p are underdeterred since they cannot pay h/p ; by raising c , p is raised, and more such individuals are deterred; at the margin, there is a social gain of $h - pw$ from deterring an individual with wealth w . The right-hand side is the marginal cost of raising c , namely 1. The optimal p is determined implicitly by the optimal choice of c from (5).

The preceding results can be illustrated by a simple example. Suppose that the harm h if the harmful act is committed is \$20, that the benefit b from committing the act is uniformly distributed between \$0 and \$25, that the wealth w of individuals is uniformly distributed between \$0 and \$100,000, and that the probability of detection p as a function of enforcement costs c is given by $75c$. Then it can be shown that the optimal probability of detection p^* is 0.2 and that the optimal fine f^* is \$100 (as expected, $p^*f^* = h = \$20$).⁵ Thus, everyone with wealth less than \$100 pays his wealth, while everyone with wealth greater than this level pays the fine of \$100. Given the assumption that wealth is uniformly distributed between \$0 and \$100,000, the optimal fine is less than the wealth of more than 99 percent of the population and is less than 1 percent of the wealth of the highest-wealth individuals.

II. Comments

(a) As noted above, the assumption that the probability of detection is the same for individuals with different wealth is central

to our results. If the probability could be chosen independently for individuals with different levels of wealth, then, for each level of wealth w , the optimal fine would be the entire wealth w . The reason is that Becker's argument would apply for each w : if $f^*(w) < w$, then by raising f to w and lowering p from $p^*(w)$ to the p such that $pw = p^*(w)f^*(w)$, deterrence would not be affected, but enforcement costs would fall.

However, for many harmful acts, the probability of detection does seem to be largely independent of wealth. This may be because it is difficult to vary enforcement effort with respect to individuals' wealth. For example, there obviously are limits to our ability to make the probability of detecting traffic violations depend on the wealth of drivers. In these kinds of circumstances, a fine less than the wealth of many individuals generally will be optimal for the reasons explained in this note.

(b) The assumption that the benefits obtained by individuals who commit the harmful act are included in social welfare is necessary for our conclusions. If individuals' benefits did not count in social welfare, it would be desirable to deter all harmful acts. Consequently, it would always be optimal to impose the highest possible fine, that is, a fine equal to wealth.

(c) If the sanction were imprisonment rather than a fine, the results would be analogous to those discussed here. Suppose individuals vary in terms of their age, and therefore in terms of the maximum imprisonment term that can be imposed on them. Then the analogue to our result would be that the optimal imprisonment term generally would be less than the maximum imprisonment term that could be imposed on the youngest offenders.

Standards versus Standards: The Effects of Different Pollution Restrictions

By GLORIA E. HELFAND*

When economists refer to pollution standards, they almost universally mean uniform restrictions on pollution emissions (e.g., William J. Baumol and Wallace E. Oates, 1975 Ch. 13; Susan Rose-Ackerman, 1973; David Besanko, 1978). However, in practice, standards take many forms: not only emissions restrictions, but restrictions on pollution per unit of output or per unit of an input, restrictions on the use of a polluting input, or mandated use of a particular pollution-control technology. These specifications of regulations will have a variety of effects on a firm's resource-allocation decisions. For instance, allowing pollution per unit of output as the standard instead of directly restricting the level of pollution gives the firm some choice: in addition to reducing pollution, it can increase its output to "dilute" the pollution.

This paper examines the effects of five different forms of pollution standards on input decisions, the level of production, and firm profits. The results show that the different standards, by providing firms with different incentives, change the firm's allocation decisions and affect the relative profitability of the standards. Section I reviews the existing literature on the incentives of different instruments. The following section describes the model to be used. Five different forms of pollution constraints are individually examined in Section III using a graphical approach. Their relative effects,

as well as some special cases, are assessed in Section IV. Finally, Section V raises the case of different standards when firms are not identical.

I. Different Standards and What Is Known of Them

The forms of standards used in actual regulations vary tremendously. A review of various state and federal regulations would show that standards are set in terms of such units as the total level of emissions per unit time, the amount of emissions per unit of output or input, requirements for certain pollution-control technologies, and restrictions on polluting inputs (Clifford S. Russell et al., 1986 pp. 17-19; Helfand, 1988 Ch. 2).

While the pollution-control literature includes analysis involving many of these forms, the correspondence between frequency of use in the literature and frequency of use in the standards is not perfect. For instance, while the literature includes examples of standards expressed as restrictions on output (e.g., James M. Buchanan and Gordon Tullock, 1975), no example of such a standard was found in any regulations reviewed. Many national regulations are set in terms of emissions per unit of output or input, but relatively few articles use that form of standard (Eithan Hochman and David Zilberman [1978] is an exception). Standards with such varied forms must inevitably provide firms with different incentives. Studies that examine the effects of a particular standard may not generalize to other forms of standards.

A few studies have examined pieces of this problem, but no one study has looked in a general way at the range of standards in use. Jon D. Harford and Gordon Karp (1983) compared the efficiency of standards expressed as pollution per unit of output

*Assistant Professor, Department of Agricultural Economics, University of California, Davis, Davis, CA 95616. I thank Peter Berck, Larry Karp, Jonathan Rubin, David Zilberman, Susanne Scotchner, seminar participants at the University of Illinois, the University of California at Berkeley, the University of California at Davis, and Duke University, and two anonymous referees for their helpful comments. This is Giannini Foundation Paper No. 950.

and pollution per unit of input. Their model, which held output and total emissions fixed, found that the pollution-per-output standard was more efficient because it least distorted the input mix.

Vinod Thomas (1980) compared the welfare costs of an emissions standard to several other forms of regulation for the steel industry near Chicago: a set level of pollution-control expenditures, restricting the polluting input (fuel), and restricting emissions as a function of fuel. The welfare costs of these other policies, except the input restriction, were estimated to be 30–40 percent higher than those of the emissions standard, though only 1–1.4 percent of the value of steel output; direct restriction of the fuel input had a welfare cost of about 30 percent of the value of output. Thomas concluded that the choice of a standard could have a significant effect on the efficiency costs of environmental regulation.

Besanko (1987) analyzed the effects of restricting pollution (a “performance” standard) versus mandating a specific level of pollution-control technology (a “design” standard). For N symmetric Cournot firms, the performance standard resulted in higher profits for the individual firms, but output was higher under the design standard. If social welfare is defined as the sum of producer and consumer surplus, neither standard unambiguously produced higher welfare than the other: the greater output under the design standard enhanced consumer surplus, even as it reduced producer surplus.

The articles by Harford and Karp and by Besanko look only at subsets of possible standards, while the article by Thomas examines the effect of a range of standards only for one industry. Because the models used in these studies have different assumptions, the results are not directly related. The present study reviews a range of standards in the context of one model to compare their effects unambiguously.

II. The One-Firm Model

The model used here involves one firm, facing a horizontal output demand curve

and using two inputs, x_1 and x_2 , with horizontal supply curves. While the assumption that there are only two inputs is a simplification, made to keep the comparative statics and the graphical presentation simple, the problem is likely to generalize to N inputs with few differences. The assumption of a horizontal output demand curve is more limiting. Made to keep the problem tractable and to permit a graphical presentation, it is realistic only for a good whose world price is unaffected by production in this country. It deserves to be lifted in future work.

The firm is assumed to produce an output f using the production function $f(x_1, x_2)$. It is initially assumed that $f_i > 0$ for $i = 1, 2$,¹ that is, both inputs contribute to production. Additionally, $f_{ii} < 0$ for both i , and the Hessian of the production function is negative definite; that is, both inputs and the production function are subject to diminishing marginal returns.

The firm also produces pollution $A(x_1, x_2)$. It is initially assumed that input 1 increases pollution (i.e., $A_1 > 0$), while input 2 decreases pollution ($A_2 < 0$). For instance, input 1 can be thought of as coal used in electricity generation, and input 2 as water used both to turn the turbines for electricity and to cool thermal discharges.

The firm is assumed to maximize profits while facing an output price p and input prices w_1 and w_2 , corresponding to inputs 1 and 2, respectively. They are assumed to be fixed for this analysis.

Before a pollution-control constraint is imposed, the firm is assumed to maximize profits, π . The unconstrained problem becomes

$$(1) \quad \max_{x_1, x_2} \pi = pf(x_1, x_2) - w_1x_1 - w_2x_2$$

which results in a solution $x^0 = (x_1^0, x_2^0)$; it is unique, since the production function is strictly concave.

¹Subscripts in this and future cases denote derivatives with respect to i .

FIGURE 1. EFFECTS OF DIFFERENT POLLUTION-CONTROL STANDARDS

This result can be displayed on a diagram like one used for isoquant analysis, such as Figure 1. The polluting input, x_1 , is measured along the horizontal axis, while the pollution-abating input, x_2 , is measured along the vertical axis. The profit-maximizing combination of these inputs is found at x^0 , which implicitly lies at the tangency of an isoquant $f^0 = f(x_1^0, x_2^0)$ with an isocost line whose slope is $-w_1/w_2$.

Because of the uniqueness of this maximum, isoprofit contours (i.e., contours representing input combinations yielding the same level of profits) can be drawn on the diagram as well. That these contours are convex rings can be derived from the assumed strict concavity of the production function. The maximum-profits point x^0 can be considered the top of a profits hill. Iso-profit contours away from this point are decreasing levels of profits with movement down the profits hill.

An isopollution line (i.e., a line representing input combinations giving a fixed level

of pollution) can be added to this diagram. Totally differentiating the function $A^0 = A(x_1, x_2)$ gives the slope of this line as $dx_2/dx_1 = -A_1/A_2$, which is positive since $A_1 > 0$ and $A_2 < 0$. In other words, as use of the polluting input increases, use of the abating input must also increase in order to maintain a constant level of pollution. Isopollution contours above and to the left of another contour represent lower levels of pollution: for a given amount of the pollution-abating input, pollution decreases as use of the polluting input decreases. In Figure 1, the initial level of pollution is represented by the line $A^0 = A(x_1^0, x_2^0)$. The line A^1 , above and to the left of the original contour, represents a lower level of pollution.

III. The Constraints

Five different kinds of pollution-control standards will be examined here: a fixed level of emissions, a fixed level of emissions

per unit of output, a fixed level of emissions per unit of an input, a fixed level of output, and a fixed level of an input.² In two of these cases (pollution per input and fixing the level of an input), two subcases will be analyzed, reflecting the different inputs used here. These formulations include most of the standards analyzed by Thomas (1980), Harford and Karp (1983), and Besanko (1987), as well as others used in either the pollution-control literature or environmental regulation.

One way to analyze the effects of each constraint relative to the baseline of no regulation is to set up the profit-maximization problem, differentiate totally the first-order conditions, and use comparative statics to analyze the effects of the constraint on the level of input use, output, profits, and pollution. Identical results can be derived from a graphical analysis. Since a graphical approach is easier to interpret, it will be used to present the results; the comparative-statics analysis can be obtained from the author.

A. Standard as a Set Level of Emissions

Let Z_P be the numerical standard set when emissions are regulated by the amount of total pollution permissible in a certain period of time. It can be represented as a constraint on the profit function with the form $A \leq Z_P$.

Figure 1 presents the graphical interpretation of this problem. The point $x^0 = (x_1^0, x_2^0)$ is the previously described unconstrained-maximum-profits locus. The addition of the constraint requires that the firm

choose inputs that will place it on a leftward isopollution line, such as A^P . Since the firm will nevertheless seek to maximize profits, it will choose the point of the new isopollution line that achieves the highest level of profits: the point where the isopollution line is tangent to the highest attainable isoprofit line. This point is represented by $x^P = (x_1^P, x_2^P)$.

In general, as Figure 1 shows, use of the polluting input should decrease, and use of the pollution-abating input should increase. These results are expected, since the purpose of the constraint is to reduce pollution. However, use of the polluting input may actually increase, or use of the abating input may decrease. These seemingly perverse results depend on the actual shape of the isoprofit contours: the tangency between the isoprofit and isopollution line may lie above and to the right, or below and to the left, of x^0 . Mathematically, these results depend on the sign and magnitude of the f_{12} term, the effect on the marginal product of input 1 as use of input 2 changes. All that is known theoretically about this term is that $f_{11}f_{22} > (f_{12})^2$ for a strictly concave production function. This information is not sufficient to determine more about the effects of this constraint on input use.

Because use of one input is increasing and use of the other is decreasing, the effects on production are ambiguous. Profits are unambiguously lower under this standard, since the firm can always do better in an unconstrained situation than in a constrained one. Pollution, by definition of the constraint, is reduced.

B. Standard as Emissions per Unit of Output

Let Z_{PF} be the standard expressed as a set level of pollution per unit of output, or $A/f \leq Z_{PF}$. Totally differentiating the constraint equation gives the slope of the constraint line, $dx_2/dx_1 = -(fA_1 - f_1A)/(fA_2 - f_2A)$. The denominator is negative according to the assumptions on signs; $fA_1 - f_1A$ is positive if $A_1/(A/x_1) > f_1/(f/x_1)$. If A is convex in input 1 (indicating that

²These standards are not always as different as they first appear. For instance, a regulatory agency may develop a standard based on a particular cleanup technology (fixing an abating input) but express that standard in other units, such as pollution per unit of output. Indeed, the technology standard may de facto be mandated by the pollution-per-output standard. This analysis assumes that expression of the standard as pollution per unit gives the firm the choice of using alternative approaches.

pollution increases more rapidly as use of the polluting input increases), the marginal amount of pollution is greater than the average amount at any given point, and $A_1/(A/x_1)$ is greater than one. On the other hand, f is assumed to be concave in input 1; by analogous reasoning, the marginal product is less than the average product, and the ratio is less than 1. Therefore, $fA_1 - f_1A$ is positive, and the slope of this standard is positive.

The slope of this constraint line can be compared to the slope of the isopollution contour by subtraction:

$$\frac{dx_2}{dx_1}(Z_{PF}) - \frac{dx_2}{dx_1}(Z_P) = \frac{(f_1A_2 - f_2A_1)}{(fA_2 - f_2A)A_2} < 0$$

by the assumed signs of these terms. Though this line slopes upward, it slopes upward at a lesser angle than does the isopollution contour.

This new constraint is also illustrated in Figure 1. If the standard is normalized to achieve the same level of pollution as standard P, its constraint line must intersect the isopollution line at the constraint's tangency with the highest possible isoprofit contour. This fact, plus the fact that its slope is shallower than that of the isopollution line, can establish the location of this constraint. If it were along the same isoprofit contour as is standard P, then the tangency would be to the right of the tangency for standard P, x^P ; however, if it were along that isoprofit contour, then it could not be on the same isopollution line, since it would lie above that isoprofit contour except at x^P . Therefore, the combination of inputs that maximizes profits while achieving standard PF, $x^{PF} = (x_1^{PF}, x_2^{PF})$, is above and to the right of the combination for standard P along the isopollution line A^P .

In the "normal" case, use of the polluting input should drop, and use of the abating input should increase. As with the pollution standard, though, it is possible that use of

the polluting input may increase or that use of the abating input may decrease. These results depend, as with the pollution constraint, on the sign and the magnitude of the f_{12} term. The effects on production remain ambiguous; profits unambiguously decrease. Finally, the effects of this standard on pollution levels are somewhat ambiguous, depending on the sign and magnitude of the f_{12} term: if production increases more rapidly than pollution, then this constraint could lead to the perverse result that pollution increases with its imposition.

C. Standard as Emissions per Unit of a Specified Input

The mathematical representation of this standard is $A/x_j \leq Z_{PJ}$, $J = 1$ or 2 , where J is the subscript for the input in terms of which pollution is measured. Two cases are possible here: regulating pollution per unit of a pollution-causing input, such as restricting the amount of sulfur dioxide emissions per ton of coal used for electricity; or regulating pollution per unit of a pollution-reducing input, such as regulating biological oxygen demand in water pollution per unit of water in a production process. Wesley A. Magat et al. (1986 p. 35) note that the Environmental Protection Agency (EPA) preferred a pollution-per-output standard to the latter form, out of concern that plants would meet the standard solely by dilution and not by cleanup.

Let PPI represent the situation in which pollution is regulated per unit of the polluting input, and let PAI represent pollution regulated in terms of the pollution-abating input. The slope for $Z_{PPI} = A/x_1$ is $-(A_1x_1 - A)/A_2x_1$ which is positive if $A_1 > A/x_1$. By the same reasoning used for $f_1A - fA_1$ in the pollution-per-output case above, the marginal pollution at any given level of inputs is greater than the average level if A is convex in the polluting inputs. Thus, $A_1x_1 - A$ is positive, and this slope is positive. For $Z_{PAI} = A/x_2$, the slope is $-A_1x_2/(A_2x_2 - A) > 0$. As with pollution per output, the slopes of these constraint lines can be compared with that of the

isopollution line:

$$(2) \quad \frac{dx_2}{dx_1}(Z_{PPI}) - \frac{dx_2}{dx_1}(Z_P) = \frac{A}{A_2 x_1} < 0$$

$$\frac{dx_2}{dx_1}(Z_{PAI}) - \frac{dx_2}{dx_1}(Z_P)$$

$$= \frac{AA_1}{A_2(A - A_2 x_2)} < 0.$$

Clearly the slopes of the constraint lines are less than the latter slope. However, no clear comparison of slopes is possible between these two standards or between either of these standards and the pollution-per-output standard: none of the following comparisons can be signed:

$$(3) \quad \frac{dx_2}{dx_1}(Z_{PPI}) - \frac{dx_2}{dx_1}(Z_{PAI})$$

$$= \frac{A(A_1 x_1 + A_2 x_2 - A)}{A_2 x_1(A_2 x_2 - A)}$$

$$\frac{dx_2}{dx_1}(Z_{PPI}) - \frac{dx_2}{dx_1}(Z_{PF})$$

$$= \frac{A[A_2(f - f_1 x_1) + f_2(A_1 x_1 - A)]}{A_2 x_1(f A_2 - f_2 A)}$$

$$\frac{dx_2}{dx_1}(Z_{PAI}) - \frac{dx_2}{dx_1}(Z_{PF})$$

$$= \frac{A[A_1(f_2 x_2 - f) + f_1(A - A_2 x_2)]}{(A_2 x_2 - A)(f A_2 - f_2 A)}.$$

The numerator of the slope difference between standards PPI and PAI would be zero if the pollution function had constant returns to scale (since, by Euler's law, $A = A_1 x_1 + A_2 x_2$ if the function has constant returns to scale); however, without assumptions about the returns to scale of this function, it cannot be signed. It nevertheless indicates that these returns determine any

differences between these functions: increasing returns makes the PAI standard line steeper, and decreasing returns make PPI have a steeper slope. Somewhat similarly, if both the production and the pollution functions have constant returns to scale, then the numerators of the comparisons between either pollution-per-input standard and the pollution-per-output standard would be zero as well.³ Thus, comparison of either standard with the constraint line for standard PF requires further knowledge of the relative returns to scale for both the pollution and the production functions.

Because the constraint lines of these three standards (pollution per unit of output and pollution per unit of either input) cannot be readily distinguished from each other, the remainder of this analysis will not distinguish among them. These three formulations of the standard will be referred to as the "dilution" standards, since they all involve measuring pollution diluted by either output or input. The point x^P in Figure 1 thus reflects the effects of standards PPI and PAI as well as it reflects the effects of standard PF.

D. Standard as a Set Level of Total Output

This standard forces the firm to reduce output; input substitution alone is inadequate. The constraint is now $f \leq Z_F$. This formulation of the standard mandates that the firm operate on an isoquant closer to the origin than the profit-maximizing isoquant. The firm will operate with the input mix given by the point of tangency of that downward-sloping isoquant with the highest possible isoprofit curve, represented by the point $x^F = (x_1^F, x_2^F)$. Because of the negative slope of the isoquant, this tangency must be below and to the left of x^P .

³With constant returns, $f - f_1 x_1 = f_2 x_2$, and $A_1 x_1 - A = -A_2 x_2$; the numerator of $(dx_2/dx_1)(Z_{PPI}) - (dx_2/dx_1)(Z_{PF})$ becomes zero. A similar analysis can be done for the terms in the comparison of standard PAI and standard PF.

Use of both inputs will generally decrease, though as before, exceptions are possible, depending on f_{12} . By definition, output decreases, and profits decline as usual, because the firm is constrained away from the optimum.

It should be noted that pollution need not decrease with this standard: the new optimal input mix could end up on an isopollution curve either to the left or to the right of the initial curve, depending on whether the firm uses the polluting input or the abating input more intensively as production is reduced. It is assumed in the drawing of Figure 1 that the lower level of pollution will be achieved by a reduction in output.

E. *Standard as a Set Amount of a Specified Input*

This standard takes two forms. A maximum can be set on the use of a polluting input (standard PI); alternatively, imposing a minimum level on the use of a pollution-abating input (standard AI) captures the effect of imposing a particular pollution-control technology on a firm. Standard PI will be represented as $x_1 \leq Z_{PI}$, and standard AI will be represented as $x_2 \geq Z_{AI}$.

Graphically, the limitation on use of the polluting input is a vertical line at the chosen level of input 1; the requirement for a minimum use of the pollution-abating input results in a horizontal line at the chosen level of input 2. The vertical slope of standard PI places its optimum, x^{PI} , along A^P between x^P and x^F . The zero slope of standard AI places x^{AI} above and to the right of x^{PF} along A^P . These are shown in Figure 1.

For case PI, the limit on use of the polluting input obviously causes a reduction in the use of input 1. The effect on input 2 is ambiguous, depending entirely on the sign of f_{12} . Production will be lower if use of input 2 is not increased much, is unaffected, or decreases. Profits are obviously reduced, as in all cases. Finally, as with the output standard, pollution could either increase or decrease with the formulation of the standard, depending on the slope of the isopol-

lution line and the shape of the isoprofit contours.

For case AI, use of input 1 may either increase or decrease, depending on the sign of f_{12} . If f_{12} is nonnegative or not very negative, then production will increase through use of this standard, in contrast to the effects of standard PI. Profits decrease as usual. Finally, pollution could either increase or decrease with the use of this standard.

In sum, these different forms of pollution constraints have some similar patterns, but each has its own peculiarities. While standard AI, the minimum requirement on the abating input, may actually increase output, standard PI, the maximum requirement on the polluting input, and standard F, the restriction on output, should decrease production. The other standards have ambiguous effects on output, since they all tend to decrease use of the polluting input and to increase use of the pollution-abating input increase. Pollution unambiguously decreases only for standard P and for the dilution and input standards if f_{12} is "small" (i.e., small enough that terms involving it do not affect the sign of the function as a whole) or zero. For standard F, the effects of the restrictions on pollution are completely ambiguous. For all standards except AI, use of the polluting input is expected to drop as the pollution-control constraint is tightened; for all standards except F and PI, use of the pollution-abating input should increase.

IV. Comparisons of the Different Standards

The previous section describes the results of the different standards as they are imposed. As noted, most of the results have the same sign and are therefore initially indistinguishable. However, if the standards are normalized to achieve the same level of pollution, as they have been in Figure 1, comparisons among the standards can easily be made.

This normalization is necessary because the standards differ in form—indeed, even in units of measurement. A change of a given magnitude in one standard is not

equivalent to a change of the same magnitude in another standard. For instance, changing Z_P by one unit will change the level of pollution by one unit; however, changing Z_{PF} by one unit will result in a one-unit change in pollution per unit of output, and the results are not obviously comparable. The standards have to be normalized to reflect a common level of change. The normalization used here is to make each standard cause an identical change in the amount of pollution. The standards have been ordered along the isopollution line A^P by comparing the slopes implied by the different standards, as already discussed.

This procedure reveals a strict ordering among the standards for levels of input use and levels of output as well as some information on relative profits. The standard that most reduces input use and output levels is standard F, the restriction on output, followed by standard PI, the restriction on the polluting input. Standard PI gives the firm higher profits than does standard F. Although standard P, the restriction on pollution itself, gives the highest level of profits among any of these standards, it has lower levels of input use and output than do the dilution standards, which in turn have lower levels of input use and output (though higher profits) than result from mandating a minimum amount of the pollution-abating input.⁴

In sum, even if the individual comparative-statics results for almost all the standards are ambiguous, the orderings among the standards are clear. Though a direct restriction on pollution offers the highest profit to a firm, mandating a minimum amount of the pollution-abating input leads to the highest production, while restricting output or the polluting input causes lower levels of production.

⁴The relative levels of profits between standards F and PF, standards F and AI standards PI and PF, and standards PI and AI, cannot be determined from this analysis. On the diagram, standards F and AI and standards PI and PF are drawn on the same isoprofit contours only to keep the diagram simple.

FIGURE 2. EFFECTS OF DIFFERENT STANDARDS WHEN THE ABATING INPUT DOES NOT CONTRIBUTE TO PRODUCTION

Special Cases

These findings depend on some specific assumptions underlying the model. In particular, the assumption that the second input contributes both to production and to pollution abatement affects the differences among the standards studied here. Analysis of two special cases of the model provides some interesting contrasts with these findings.

(i) $f_2 = 0$.—In this case, it is assumed that the pollution-abating input does not contribute to production; rather, it only affects pollution. For instance, x_2 may be a pollution device attached to a smokestack that does not otherwise intervene in the production process. The isoquants are now vertical lines (since production only depends on input 1), with the unconstrained profit-maximizing point on the x_1 axis (i.e., where no use of x_2 is required, since x_2 does not contribute to production and is costly). As seen in Figure 2, assuming $f_2 = 0$ reduces the standards to two forms: x^1 , which represents the effects of a restriction of pollution (Z_P), of pollution per output (Z_{PF}), of pollution per input (Z_{PPI} or Z_{PAI}), or a required amount of the abating input (Z_{AI}); and x^2 , which results from either a restriction on the polluting input (Z_{PI}) or a restriction on output (Z_F) (since output results only from this input). Similarly to the

FIGURE 3. EFFECTS OF DIFFERENT STANDARDS WHEN THE SECOND INPUT DOES NOT ABATE POLLUTION

basic model, the standards yielding x^1 lead to higher levels of input use, output, and profits than the standards yielding x^2 .

(ii) $A_2 = 0$.—It is now assumed that the second input in the process does not abate pollution but has a neutral effect; the only way to reduce pollution is to reduce the level of the polluting input. As shown in Figure 3, the isoprofit contours are the same as in the basic model; however, the isopollution lines are vertical, since they are affected only by use of x_1 . Now, with all standards normalized to achieve A^P , restricting pollution per unit of output (Z_{PF}) and restricting pollution per unit of the second input (Z_{PAI}) have the same effect, a high level of production (x^2); restricting pollution (Z_P), restricting pollution per unit of the polluting input (Z_{PPI}), and restricting the polluting input (Z_{PI}) lead to the highest profits (x^1); and restricting output (Z_F) leads to lower levels of production (x^3). In interesting contrast to the basic case, a positive f_{12} (at point x^{4a}) causes a mandate on the second input (Z_{AI}) to have the most severe output reduction: since x_2 now does not affect pollution directly, it can only achieve the standard by inducing a reduction in use of x_1 . If f_{12} is negative (at x^{4b}),

this standard leads to the greatest increase in production, again by inducing a change in the level of x_1 .

These special cases demonstrate the dependence of these results on the assumptions of the model. If the abating input does not affect production (as would, for instance, a device attached only to a smokestack or an outfall pipe), then the standards collapse into two different levels of effects. If the only way of abating pollution is to reduce the level of the polluting input, then a range of standards is maintained, though it is not the same range as in the basic model. Any application of this model should consider the specific assumptions of the case to be analyzed, in order to account for these differences.

V. The Case of Heterogeneous Firms

The original analysis assumed that an individual firm was being regulated and that the different standards would all result in the same total level of pollution. While this analysis provides insights into the incentives of these different standards, it is not realistic. In fact, the EPA and state regulatory bodies usually set standards that apply uniformly to firms of a specific industry. Within

FIGURE 4. UNIFORM STANDARDS WITH HETEROGENEOUS FIRMS

an industry, individual firms are likely to vary by technology, size, or other factors. Given that only one form of standard is used to regulate an industry, it is unlikely that the results for the individual-firm case will carry over to the case of heterogeneous firms. This analysis will sketch some of the issues involved in choosing a standard for a number of different firms.

Assume that an industry contains three firms, all of which have the characteristics of the individual firm in the previous analysis, but which differ in optimal scale. In other words, firm 1's profit-maximizing level of output (x^1) uses less x_1 and less x_2 , and produces less output, than firm 2's profit-maximizing level of output (x^2), which in turn uses less x_1 and x_2 and produces less output than firm 3's profit-maximizing level of output, (x^3) (see Fig. 4).

Further assume that the pollution function $A(x_1, x_2)$ previously described is the same for all three firms. That is, only the inputs cause or abate pollution; the size of the firm itself does not have a direct effect on how much a firm pollutes. Thus, if firm 1

chose to operate with the same input mix as firm 2, it would pollute the same amount as firm 2. Under normal operating conditions, though, the level of pollution will change with the firm, since the firms use different levels of x_1 and x_2 .

This assumption simplifies a graphical analysis. Because most of the standards addressed in this study (in particular, the pollution standard, the pollution-per-input standards, and the input standards) rely only on the levels of the inputs and the pollution function; they do not depend on the level of output and, therefore, do not depend on the technology of the firm. As a result, one constraint can be drawn onto an isoquant diagram and will apply equally to all firms.⁵

⁵The pollution-per-output standard and the output standard will clearly have effects that depend on what technology a firm uses. For instance, these firms may have isoquants that cross each other. With these two standards, a single constraint line cannot be used, complicating a graphical analysis. For present purposes, these constraints will not be considered. While ignoring the output constraint does not have significant

Because the pollution-per-input standard⁶ is commonly used, while the pollution standard is heavily used in the economics literature, this analysis will focus on these two standards.

Firms are in compliance with the standards if they lie above or to the left of the constraint lines appropriate for the form of standard chosen. They initially violate the standards and must readjust their operations if they lie below or to the right of the constraint lines.

Figure 4 shows the constraint lines for these two standards. As in the single-firm analysis, the pollution constraint slopes upward, while the pollution-per-input standard slopes upward but more shallowly. (These relationships still hold, since both of these constraints depend only on the levels of input use.)

Where a firm lies on the diagram determines whether it has to adjust its production to comply with the constraints. In this diagram, firm 2 is in exact compliance with both standards; firm 1 satisfies the pollution standard but not the pollution-per-input standard; and firm 3 meets the pollution-per-input standard but not the pollution standard.

In the one-firm analysis, all the standards were oriented to produce the same total emissions from the one firm. Here, instead of making emissions per firm constant, the total level of pollution from all the firms will be held constant. This analysis will describe how to make such a normalization.

Let Z^P be the level of pollution specified by the pollution standard, and let A^{ij} represent the absolute value of the deviation from Z^P for firm j ($j=1,2,3$) under standard i ($i=P,PI$; where PI is pollution per unit of input for this analysis). Under the

pollution standard, firm 3 will have to reduce its pollution to Z^P to meet the standard, while firm 2 already pollutes exactly Z^P . Firm 1 already has lower emissions than this standard: it underpollutes by A^{P1} . Thus, total pollution under the pollution standard (TP_P) is $TP_P = 3Z^P - A^{P1}$.

Under the pollution-per-input standard, firm 1 has to clean up to meet the standard, even with its relatively low emissions. In contrast, firm 3 satisfies the standard and does not have to abate its emissions, though it pollutes more than Z^P . Total emissions under this standard (TP_{PI}) are

$$(4) \quad TP_{PI} = 3Z^P - A^{PI1} + A^{PI3}.$$

For total emissions to be the same under both standards, then $TP_P = TP_{PI}$, or

$$(5) \quad A^{PI1} - A^{P1} = A^{PI3}.$$

This normalization is approximated in Figure 4. In general, an exact normalization would require more complete knowledge of how changing the level of pollution changes the distance between the isopollution lines.

The effects of the different standards on the levels of input use, output, and profits for an individual firm relative to the non-pollution baseline follow the patterns of the one-firm analysis, with a notable exception: the small firm is completely unaffected by the pollution standard, while the large firm must adjust its behavior; in contrast, the pollution-per-input standard forces the small firm to adjust its behavior and leaves the large firm unaffected.

Comparisons between the standards are more interesting, but they are also more difficult to make, since they depend heavily on the shapes of the isoprofit contours. In the one-firm analysis, the pollution-per-input standard uses more of both inputs than the pollution standard, resulting in more output, though it gives the firm lower profits. With heterogeneous firms, however, similar conclusions cannot be drawn. Indeed, virtually any change in aggregate input use is possible. For instance, the shallower slope of the pollution-per-input standard may appear to induce less reduction in the polluting input and more increase in the

policy results, since this standard is not commonly used, further analysis of the common pollution-per-output standard is desirable.

⁶As seen in the one-firm analysis, the effects of measuring pollution per unit of the abating input are difficult to distinguish from the effects of measuring pollution per unit of the polluting input. For the purposes of this analysis, no distinction is drawn between the two.

abating input for the small firm than the pollution standard induces for the large firm. However, the "perverse" cases of the one-firm analysis can reverse this appearance. If the large firm increases its use of the polluting input or the small firm reduces its use of the abating input, then the relative change in total use of the inputs under the two standards cannot be determined. The shapes of the isoprofit contours for the firms, as well as the exact slopes of the two constraints, will determine the relative effects.

Because input comparisons cannot be made definitively, the effects of the different standards on output cannot be assessed. Finally, the relative effects on aggregate profits cannot be determined. If one firm has a shallower "profit hill" than the other (i.e., if profits for one firm decrease less rapidly than for the other when the profit-maximizing input mix is no longer available), then that firm is less likely to be severely hurt by either pollution standard. There is no obvious reason for smaller firms to have steeper profit hills than larger firms; as a result, no clear comparison can be made.

Perhaps the major conclusion from Figure 4 is that the effects of the different standards depend on the size of the firm in question. If pollution increases with output, even if not in direct proportion, then the large firm is more likely to have to adjust to a pollution standard than will the small firm.⁷ In contrast, a pollution-per-input standard "dilutes" the effect of pollution increasing with scale, because use of the input also increases with scale; the large firm is thus less likely to be penalized under this standard than under the pollution standard. The small firm may violate the pollution-per-input standard, even though it pollutes relatively small amounts.

⁷As drawn, pollution does increase with output, since the expansion path for firm scale has a flatter slope than the isopollution line. For output to increase while pollution declines, the slope of this expansion path would have to be steeper than the slope of the isopollution line. While such a scenario is possible if the expansion path is relatively intensive in input 2, it is generally more likely that larger firms pollute more than smaller firms.

These two standards provide different incentives for firms entering and exiting the industry. If pollution does increase with the size of the firm, then the pollution standard will put more pressure on large firms; they are more likely to exit, and small firms are more likely to enter. In contrast, the pollution-per-input standard will lead to larger firms entering the industry and smaller firms exiting. Ironically, this standard could lead to increased pollution, since large firms can comply with the pollution-per-input standard and still pollute more than small firms. The PI standard would have to become increasingly strict to maintain a lower level of emissions, which would in turn induce new firms to be even larger. The uniform pollution standard would have to be adjusted as the number of firms in the industry changed, but it would obviously not lead to more pollution per firm.

VI. Summary and Conclusions

This study has reviewed the effects of five different forms of pollution-control standards. It has shown in the basic model that a direct restriction on pollution leads to the highest level of profits and efficiency when all pollution standards are set to achieve the same level of emissions; a mandate for use of a pollution-abating input leads to highest output, followed by pollution per unit of output or input; and a restriction on production most reduces output, followed by a restriction on the polluting input. Besanko (1987) similarly found that firms profit most from a pollution restriction, though a mandate for an abating input might increase social welfare by increasing output. Thomas's (1980) simulation found the welfare costs of a pollution restriction to be lower than those of other standards, especially those of a mandate on the polluting input. If the results of this study apply to his model as well, then the combination of reduced profits for a firm and reduced output lead to more severe effects by reducing both consumer and producer surplus. Finally, Harford and Karp (1983) focused on comparisons of a pollution-per-output standard versus pollution per input and found the former to be more efficient than the latter,

since it leads to less distortion in input use. The present study, in contrast, found no easily distinguishable differences between these standards (without assumptions on the relative returns to scale of the production and pollution functions): both produce more output than the pollution standard, though both also produce lower profits. The disparity between studies is probably caused by Harford and Karp's assumption of fixed output: while only input ratios could be inefficient in their study, the output level can be inefficient here as well. Given that the results of the other studies are all derived from different models, the similarities in the results outweigh the differences.

The present analysis has also shown that altering the underlying assumptions of the model affects the comparisons of the standards. Any application of this model must consider the specific characteristics of the case to be studied in order to account for the differences caused by different assumptions.

Finally, when a single regulation is imposed on an industry composed of non-identical firms, the chosen standard will not affect all firms identically. The scale, input intensity, and pollution intensity of the firm, among other factors, will determine whether it will satisfy various standards. The chosen standard can thus have an effect on the optimal structure of the firm and may play a role in the entry and exit decisions of firms.

Willingness To Pay and Willingness To Accept: How Much Can They Differ?

By W. MICHAEL HANEMANN*

In many empirical studies, analysts seek to obtain money measures of welfare changes due not to price changes but to changes in the availability of public goods or amenities, changes in the qualities of commodities, or changes in the fixed quantities of rationed goods. The conventional welfare measures for price changes are the compensating (*C*) and equivalent (*E*) variations, which correspond to the maximum amount an individual would be willing to pay (WTP) to secure the change or the minimum amount she would be willing to accept (WTA) to forgo it. Karl-Göran Mäler (1974) was perhaps the first to show that the concepts of *C* and *E* can readily be extended from conventional price changes to such quantity changes. For price changes, Robert Willig (1976) demonstrated that *C* and *E* are likely to be fairly close in value, with the difference depending directly on the size of the income elasticity of demand for the commodity whose price changes. Subsequently, Alan Randall and John Stoll (1980) examined the duality theory associated with fixed quantities in the utility function and showed that, with appropriate modifications, Willig's formulas for bounds on *C* and *E* do, indeed, carry over to this setting.

Within the environmental-economics literature, Randall and Stoll's results have been widely interpreted as implying that WTP and WTA for changes in environmental amenities should not differ greatly unless there are unusual income effects.¹ However,

recent empirical work using various types of interview procedures has produced some evidence of large disparities between WTP and WTA measures.² This has led to something of an impasse: how can the empirical evidence of significant differences between WTP and WTA be reconciled with the theoretical analysis suggesting that such differences are unlikely? Can they be explained entirely by unusual income effects or by peculiarities of the interview process?

In this note, I reexamine Randall and Stoll's analysis and show that, while it is indeed accurate, its implications have been misunderstood. For quantity changes, there is no presumption that WTP and WTA must be close in value and, unlike price changes, the difference between WTP and WTA depends not only on an income effect but also on a substitution effect. By the latter, I mean the ease with which other privately marketed commodities can be substituted for the given public good or fixed commodity, while maintaining the individual at a constant level of utility. I show that, holding income effects constant, the smaller the substitution effect (i.e., the fewer substitutes available for the public good) the greater the disparity between WTP and WTA. This surely coincides with common intuition. If there are private goods that are readily substitutable for the public good, there ought to be little difference between an individual's WTP and WTA for a change in the public good. However, if the public good has almost no substitutes (e.g., Yosemite National Park, or in a different context, your own life), there is no reason why WTP and WTA could not differ vastly: in the limit, WTP could equal the individual's entire (finite)

income, while WTA could be infinite. My argument is developed in the following two sections. Section I deals specifically with the two polar cases of perfect substitution and zero substitution between the public good and available private goods. Section II deals with Randall and Stoll's extension of Willig's formulas and shows that their bounds are, in fact, consistent with substantial divergences between WTP and WTA. Section III presents empirical application of these bounds and relates them to Mäler's concept of weak complementarity.

I. Two Polar Cases

The theoretical setup is as follows. An individual has preferences for various conventional market commodities whose consumption is denoted by the vector \mathbf{x} as well as for another commodity whose consumption is denoted by q .³ This could represent the supply of a public good or amenity; it could be an index of the quality of one of the private goods; or it could be a private commodity whose consumption is fixed by a public agency.⁴ The key point is that the individual's consumption of q is fixed exogenously, while she can freely vary her consumption of the \mathbf{x} 's. These preferences are represented by a utility function, $u(\mathbf{x}, q)$, which is continuous and nondecreasing in its arguments (I assume that the \mathbf{x} 's and q are all "goods") and strictly quasiconcave in \mathbf{x} . The individual chooses her consumption by solving

$$(1) \quad \max_{\mathbf{x}} u(\mathbf{x}, q) \text{ subject to } \sum p_i x_i = y$$

taking the level of q as given. This yields a set of ordinary demand functions, $x_i = h^i(\mathbf{p}, q, y)$, $i = 1, \dots, N$, and an indirect utility function, $v(\mathbf{p}, q, y) \equiv u[h(\mathbf{p}, q, y), q]$,

³I am treating q as a scalar here, but it could be a vector without seriously affecting the analysis in this section. In the next section, however, the analysis would become significantly more complex if q were a vector and more than one element of q changed.

⁴These alternative interpretations are offered, respectively, by Mäler (1974), Hanemann (1982), and Randall and Stoll (1980).

which has the conventional properties with respect to the price and income arguments and also is nondecreasing in q .⁵ Now suppose that q rises from q^0 to $q^1 > q^0$ while prices and income remain constant at (\mathbf{p}, y) . Accordingly, the individual's utility changes from $u^0 \equiv v(\mathbf{p}, q^0, y)$ to $u^1 \equiv v(\mathbf{p}, q^1, y) \geq u^0$. Following Mäler, the compensating and equivalent variation measures of this change are defined, respectively, by⁶

$$(2) \quad v(\mathbf{p}, q^1, y - C) = v(\mathbf{p}, q^0, y)$$

$$(3) \quad v(\mathbf{p}, q^1, y) = v(\mathbf{p}, q^0, y + E).$$

Dual to the utility maximization in (1) is an expenditure minimization: minimize $\sum p_i x_i$ with respect to \mathbf{x} subject to $u = u(\mathbf{x}, q)$, which yields a set of compensated demand functions, $x_i = g^i(\mathbf{p}, q, u)$, $i = 1, \dots, N$, and an expenditure function, $m(\mathbf{p}, q, u) \equiv \sum p_i g^i(\mathbf{p}, q, u)$, which has the conventional properties with respect to (\mathbf{p}, u) and is non-increasing in q . In terms of this function, C and E are given by

$$(2') \quad C = m(\mathbf{p}, q^0, u^0) - m(\mathbf{p}, q^1, u^0)$$

$$(3') \quad E = m(\mathbf{p}, q^0, u^1) - m(\mathbf{p}, q^1, u^1).$$

It is evident from (2) and (3) that $0 < C < y$ while $E \geq 0$.⁷ The questions at issue are: i) is it true that $E/C \approx 1$? and ii) what factors affect this ratio? As a first cut at an answer, I compare two polar cases. In the first case, at least one private good—say, the first—is a perfect substitute for some

⁵These properties are established in my earlier paper (Hanemann, 1982).

⁶I have taken the liberty of defining C and E as the negative of quantities appearing in Willig (1976) and in Randall and Stoll (1980), so that $\text{sign}(C) = \text{sign}(E) = \text{sign}(u^1 - u^0)$.

⁷I assume throughout that $q^1 > q^0$ and $u^1 \geq u^0$. The analysis could be repeated for a case in which quality decreases and $u^1 < u^0$. In that case, C and E are both nonpositive and correspond, respectively, to the compensation that the individual would be willing to accept to consent to the change and the amount that she would be willing to pay to avoid the change. This would reverse the inequalities presented in what follows, but it would not affect the substance of my argument.

transformation of q . Thus, the direct utility function assumes the special form

$$(4) \quad u(\mathbf{x}, q) = \bar{u}[x_1 + \psi(q), x_2, \dots, x_N]$$

where $\psi(\cdot)$ is an increasing function and $\bar{u}(\cdot)$ is a continuous, increasing, strictly quasi-concave function of N variables. As W. M. Gorman (1976) has shown, assuming an interior solution, the resulting indirect utility function is

$$(5) \quad v(\mathbf{p}, q, y) = \bar{v}[p_1, p_2, \dots, p_N, y + p_1 \cdot \psi(q)]$$

where $\bar{v}(\cdot)$ is the indirect utility function corresponding to $\bar{u}(\cdot)$. Substitution of (5) into (2) and (3) yields the following.⁸

PROPOSITION 1: *If at least one private market good is a perfect substitute for q , then $C = E$.*

At the opposite extreme, I assume that there is a zero elasticity of substitution not just between q and x_1 but between q and *all* the x 's. Thus, the direct utility function becomes

$$(6) \quad u(\mathbf{x}, q) = \bar{u}\left[\min\left(q, \frac{x_1}{\alpha_1}\right), \dots, \min\left(q, \frac{x_N}{\alpha_N}\right)\right]$$

where $\alpha_1, \dots, \alpha_N$ are positive constants and $\bar{u}(\cdot)$ is conventional direct utility function. In this case, the indirect utility function $v(\mathbf{p}, q, y)$ has a rather complex structure and changes its form in different segments of (\mathbf{p}, q, y) -space. It will be sufficient for my purposes to focus on just one of these segments. Suppose that $q \leq y / \sum p_i \alpha_i$; then, the maximization of (6), subject to the budget constraint, yields demand functions and an indirect utility function of the form $x_i = h^i(\mathbf{p}, q, y) = \alpha_i q$, and $u =$

$v(\mathbf{p}, q, y) = \bar{u}(q, \dots, q) \equiv w(q)$. In this region of (\mathbf{p}, q, y) -space, the individual does not exhaust her budget, and her marginal utility of income is therefore zero. Now suppose that $q^0 \leq y / \sum p_i \alpha_i$ and $q^1 > q^0$. Since $v(\mathbf{p}, q^1, y) > w(q^0)$, it is evident from (2) that the individual would be willing to pay some positive but limited amount C to secure this change. However, for any positive quantity E , no matter how large, $v(\mathbf{p}, q^0, y + E) = v(\mathbf{p}, q^0, y) = w(q^0)$. This implies the following proposition.

PROPOSITION 2: *If there is zero substitutability between q and each of the private-market goods, it can happen that, while the individual would only be willing to pay a finite amount for an increase in q , there is no finite compensation that she would accept to forgo this increase.*

It should be emphasized that this result obtains only in a portion of (\mathbf{p}, q, y) space; in other regions, even with (6), E would be finite.⁹ However, the result in Proposition 2 can also be established for other utility functions that permit some substitutability between q and the x 's as long as the indifference curves between q and each of the x 's become parallel to the x axis at some point. The implication of these two propositions is that the degree of substitutability between q and private-market goods *does* significantly affect the relation between C and E . In the next section, I show how this observation can be reconciled with the bounds on C and E derived by Randall and Stoll.

II. Randall and Stoll's Bounds

In order to extend Willig's bounds from price to commodity space, Randall and Stoll focus on a set of demand functions different from those considered above. Suppose that the individual could purchase q in a market

⁸This result carries over, of course, if *more* than one private good is a perfect substitute for q . In the most general case, $u(\mathbf{x}, q) = \bar{u}[x_1 + \psi_1(q), \dots, x_N + \psi_N(q)]$ and $C = E = \sum p_i [\psi_i(q^1) - \psi_i(q^0)]$.

⁹Indeed, if $\bar{h}^i(\alpha_1 p_1, \dots, \alpha_N p_N, y) \leq q^0$, $i = 1, \dots, N$, it can be shown that $v(\mathbf{p}, q^0, y) = v(\mathbf{p}, q^1, y) = \bar{v}(\alpha_1 p_1, \dots, \alpha_N p_N, y)$ and $C = E = 0$, where $\bar{h}^i(\cdot)$ and $\bar{v}(\cdot)$ are the ordinary demand functions and the indirect utility function associated with $\bar{u}(\cdot)$.

at some given price, π . It must be emphasized that this market is entirely hypothetical since q is actually a public good. Instead of (1), she would now solve¹⁰

$$(7) \max_{\mathbf{x}, q} u(\mathbf{x}, q)$$

subject to $\sum p_i x_i + \pi q = y$.

Denote the resulting ordinary demand functions by $x_i = \hat{h}^i(\mathbf{p}, \pi, y)$, $i = 1, \dots, N$ and $q = \hat{h}^q(\mathbf{p}, \pi, y)$. The corresponding indirect utility function is $\hat{v}(\mathbf{p}, \pi, y) \equiv u[\hat{h}(\mathbf{p}, \pi, y), \hat{h}^q(\mathbf{p}, \pi, y)]$. The dual to (7) is: minimize $\sum p_i x_i + \pi q$ with respect to \mathbf{x} and q subject to $u = u(\mathbf{x}, q)$. This generates a set of compensated demand functions, $x_i = \hat{g}^i(\mathbf{p}, \pi, u)$, $i = 1, \dots, N$ and $q = \hat{g}^q(\mathbf{p}, \pi, u)$, and an expenditure function, $\hat{m}(\mathbf{p}, \pi, u) \equiv \sum p_i \hat{g}^i(\mathbf{p}, \pi, u) + \pi \hat{g}^q(\mathbf{p}, \pi, u)$. These functions are hypothetical, since q is really exogenous to the individual, but they are of theoretical interest because they shed light on the relation between C and E .

For any given values of q , \mathbf{p} , and u , the equation

$$(8) \quad q = \hat{g}^q(\mathbf{p}, \pi, u)$$

may be solved to obtain $\pi = \hat{\pi}(\mathbf{p}, q, u)$, the inverse compensated demand (i.e., willingness-to-pay) function for q : $\hat{\pi}(\cdot)$ is the price that would induce the individual to purchase q units of the public good in order to attain a utility level of u , given that she could buy private goods at prices \mathbf{p} . Let $\pi^0 \equiv \hat{\pi}(\mathbf{p}, q^0, u^0)$ and $\pi^1 \equiv \hat{\pi}(\mathbf{p}, q^1, u^1)$ denote the prices that would have supported q^0 and q^1 , respectively. The two expenditure functions dual to (1) and (7) are related by

$$(9) \quad m(\mathbf{p}, q, u) \equiv \hat{m}[\mathbf{p}, \hat{\pi}(\mathbf{p}, q, u), u] \\ - \hat{\pi}(\mathbf{p}, q, u) \cdot q.$$

¹⁰ It is now necessary to assume that $u(\cdot)$ is strictly quasi-concave in both \mathbf{x} and q , rather than \mathbf{x} alone. See footnote 22 for an example in which this is a nontrivial restriction.

This implies that¹¹

$$(10) \quad m_q(\mathbf{p}, q, u) = -\hat{\pi}(\mathbf{p}, q, u).$$

Combining (10) with (2') and (3') yields these alternative formulas for C and E , expressed in terms of the willingness-to-pay function:

$$(2'') \quad C = \int_{q^0}^{q^1} \hat{\pi}(\mathbf{p}, q, u^0) dq$$

$$(3'') \quad E = \int_{q^0}^{q^1} \hat{\pi}(\mathbf{p}, q, u^1) dq.$$

It can be shown that $\text{sign}(\hat{\pi}_u) = \text{sign}(\hat{h}_y^q)$. Therefore, for given (\mathbf{p}, q) , the graph of $\hat{\pi}(\mathbf{p}, q, u^1)$ lies above (below) that of $\hat{\pi}(\mathbf{p}, q, u^0)$, and $E > (<) C$, when q is a normal (inferior) good. Figure 1 shows E and C for the case in which q is normal: E corresponds to the area $q^0 \alpha \gamma q^1$, while C corresponds to the area $q^0 \beta \delta q^1$.

Using techniques pioneered by Willig (1976), Randall and Stoll (1980) establish bounds on the difference between each of C and E and the area under an inverse ordinary demand function for q . From this, they derive bounds on the difference between C and E . However, the requisite inverse ordinary demand function is obtained in a rather special manner. Given any level of q , one can ask what market price π would induce the individual to purchase that amount of public good if it were available in a market, while still allowing her to purchase the quantity of the x 's that she actually did buy at market prices \mathbf{p} and with income y . In conducting this thought experiment, one needs to supplement the individual's income so that she can afford q as well as the x 's. Thus, for given (\mathbf{p}, q, y) , one seeks the price π that satisfies

$$(11) \quad q = \hat{h}^q(\mathbf{p}, \pi, y + \pi q).$$

¹¹ Using subscripts to denote derivatives, differentiate (9) and note that $q = \hat{g}^q(\mathbf{p}, \pi, u) = \hat{m}_\pi(\mathbf{p}, \pi, u)$ by Shephard's lemma. Equations similar to (9)–(12) are presented by J. P. Neary and K. W. S. Roberts (1980).

FIGURE 1. WTP AND WTA FOR A CHANGE IN q

The solution will be denoted by $\pi = \hat{\pi}(p, q, y)$. This inverse function is related to the inverse compensated demand function by the identities¹²

$$(12a) \quad \hat{\pi}(p, q, y) \\ \equiv \hat{\pi}[p, q, v(p, q, y)]$$

$$(12b) \quad \hat{\pi}(p, q, u) \\ \equiv \hat{\pi}[p, q, m(p, q, u)].$$

Both identities play a role in the analysis. From (12a) it follows that $\pi^0 \equiv \hat{\pi}(p, q^0, u^0) \equiv \hat{\pi}(p, q^0, y)$ and $\pi^1 \equiv \hat{\pi}(p, q^1, u^1) \equiv \hat{\pi}(p, q^1, y)$. Hence, the graph of $\hat{\pi}(p, q, y)$ as a function of q intersects the graph of $\hat{\pi}(p, q, u^0)$ at $q = q^0$, and the graph of $\hat{\pi}(p, q, u^1)$ at $q = q^1$. This is depicted in

¹²Note that $\hat{\pi}(p, q, y)$ is *not* an inverse ordinary demand function in the sense of Ronald W. Anderson (1980), because it involves an income adjustment as well as a price effect.

Figure 1.¹³ From (12b) and (10), one obtains

$$(13) \quad m_q(p, q, u) \\ = -\hat{\pi}[p, q, m(p, q, u)]$$

which is the fundamental differential equation underlying Randall and Stoll's analysis.¹⁴ Also, by differentiating (12b) and then using (13), it can be shown that the concavity of $\hat{m}(p, \pi, u)$ in π , which itself follows from the quasi-concavity of $u(x, q)$ in q , implies the following negativity condition on the Slutsky term associated with $\hat{\pi}(p, q, y)$: $\hat{\pi}_q - \pi \hat{\pi}_y \leq 0$.¹⁵

Define the quantity

$$(14) \quad A \equiv \int_{q^0}^{q^1} \hat{\pi}(p, q, y) dq$$

which corresponds to the area $q^0\beta\gamma\delta q^1$ in Figure 1. This is a sort of Marshallian consumer's surplus, which is to be compared with C and E .¹⁶ Let

$$\xi \equiv \frac{\partial \ln \hat{\pi}(p, q, y)}{\partial \ln y}$$

be the income elasticity of $\hat{\pi}(p, q, y)$; Randall and Stoll call this the "price flexibility of income." Assume that, over the range from (p, q^0, y) to (p, q^1, y) , this elasticity is bounded from below by ξ^L and from above by ξ^U , with neither bound equal to 1. Using

¹³It is commonly supposed the $\hat{\pi}_q < 0$, so that $\pi^0 > \pi^1$ when $q^0 < q^1$ (see e.g., Richard E. Just et al., 1982 fig. 7.12), but this is not correct. It can be shown that $\pi^0 \gtrless \pi^1$ according to whether $\eta \gtrless 1/\alpha$, where η and α are defined in the text below equation (16'). Since $\sum \alpha_i \eta_i + \alpha \eta = 1$ by the Engel aggregation condition, where $\alpha_i \equiv p_i \hat{h}^i(p, \pi, y + \pi q) / (y + \pi q)$ and $\eta_i \equiv (y + \pi q) \hat{h}_y^i(p, \pi, y + \pi q) / \hat{h}(p, \pi, y + \pi q)$, it follows that $\pi^0 \leq \pi^1$ if and only if $\sum \alpha_i \eta_i \leq 0$.

¹⁴This corresponds to Randall and Stoll's equation 7.

¹⁵Also, because $\hat{m}(\cdot)$ is linearly homogeneous in (p, π) , it follows that $\hat{\pi}(p, q, y)$ is linearly homogeneous in (p, y) .

¹⁶Its relation to the conventional Marshallian consumer's surplus associated with the demand for the x 's is analyzed in Proposition 4.

the mean-value theorem, as in Willig's (1976) equation 18, and integrating (13) yields Randall and Stoll's result, namely, the following.

PROPOSITION 3: Assume $\xi^L \leq \xi \leq \xi^U$ where $\xi^L \neq 1$ and $\xi^U \neq 1$. Then,

$$(i) \quad 0 \leq \left[1 + (1 - \xi^L) \frac{A}{y} \right] \frac{1}{1 - \xi^L} - 1 \leq \frac{E}{y}$$

$$(ii) \quad 0 \leq 1 - \left[1 - (1 - \xi^U) \frac{A}{y} \right] \frac{1}{1 - \xi^U} \leq \frac{C}{y} \leq 1.$$

If $\xi^U < 1$, or if $\xi^U > 1$ and $1 + (1 - \xi^U) \frac{A}{y} > 0$,

$$(iii) \quad \frac{E}{y} \leq \left[1 + (1 - \xi^U) \frac{A}{y} \right] \frac{1}{1 - \xi^U} - 1.$$

If $\xi^L > 1$, or if $\xi^L \leq 1$ and $1 - (1 - \xi^L) \frac{A}{y} \geq 0$,

$$(iv) \quad \frac{C}{y} \leq 1 - \left[1 - (1 - \xi^L) \frac{A}{y} \right] \frac{1}{1 - \xi^L}.$$

Applying a Taylor approximation, as in Willig (1976), and assuming that the conditions in (iii) and (iv) are satisfied, one obtains

$$(15) \quad \xi^L \frac{A^2}{2y} \leq E - C \leq \xi^U \frac{A^2}{2y}.$$

This is commonly interpreted as implying that C and E are likely to be close in value, but whether or not that is correct clearly depends on the magnitudes of A/y and the bounds ξ^L and ξ^U . The magnitude of A/y depends in part on the size of the change from q^0 to q^1 ; but what can be said about the likely magnitude of the income elasticity, ξ ? Could it happen, for example, that $\xi^L = \infty$? To answer that question, dif-

ferentiate (11) implicitly:

$$(16) \quad \frac{\partial \hat{\pi}(\mathbf{p}, q, y)}{\partial y} = - \frac{\hat{h}_y^q(\mathbf{p}, \pi, y + \pi q)}{\hat{h}_\pi^q(\mathbf{p}, \pi, y + \pi q) + q \hat{h}_y^q(\mathbf{p}, \pi, y + \pi q)}.$$

By the Hicks-Slutsky decomposition, the denominator is equal to the own-price derivative of the compensated demand function for q and is nonpositive:

$$\begin{aligned} \hat{g}_\pi^q[\mathbf{p}, \pi, v(\mathbf{p}, q, y)] \\ = \hat{h}_\pi^q(\mathbf{p}, \pi, y + \pi q) + q \hat{h}_y^q(\mathbf{p}, \pi, y + \pi q) \\ \leq 0. \end{aligned}$$

Converted to elasticity form, (16) becomes

$$(16') \quad \xi = - \frac{\eta(1 - \alpha)}{\varepsilon}$$

where

$$\eta \equiv \frac{(y + \pi q) \hat{h}_y^q(\mathbf{p}, \pi, y + \pi q)}{\hat{h}_\pi^q(\mathbf{p}, \pi, y + \pi q)}$$

is the income elasticity of the *direct* ordinary demand function for q ,

$$\alpha \equiv \frac{\pi \hat{h}_\pi^q(\mathbf{p}, \pi, y + \pi q)}{y + \pi q}$$

is the budget share of q in relation to "adjusted" income, and

$$\varepsilon \equiv \frac{\pi \hat{g}_\pi^q[\mathbf{p}, \pi, v(\mathbf{p}, q, y)]}{\hat{g}_y^q[\mathbf{p}, \pi, v(\mathbf{p}, q, y)]}$$

is the own-price elasticity of the compensated demand function for q .

The denominator in (16') can be related to the overall elasticity of substitution be-

tween q and the private market goods x_1, \dots, x_N . Assume that the prices p_1, \dots, p_N vary in strict proportion (i.e., $p_i = \theta \bar{p}_i$ for some fixed vector $\bar{\mathbf{p}}$ and some positive scalar θ). Let the aggregate Allen-Uzawa elasticity of substitution between q and the Hicksian composite commodity $x_0 \equiv \sum \bar{p}_i x_i$ be denoted by σ_0 . By adapting W. E. Diewert's (1974) analysis, the following formula can be established relating σ_0 to the compensated own-price elasticity for q : $\varepsilon = -\sigma_0(1 - \alpha)$.¹⁷ Hence, (16') may be written

$$(17) \quad \xi = \frac{\eta}{\sigma_0}.$$

This equation is my fundamental result. It explains the findings in the preceding section about the importance of substitution elasticities. It demonstrates that for changes in q , unlike for changes in p , the extent of the difference between C and E depends not only on income effects (i.e., η) but also on substitution effects (i.e., σ_0). If, over the relevant range, either $\eta = 0$ (no income effects) or $\sigma_0 = \infty$ (perfect substitution between q and one or more of the x 's), then $\xi^L = \xi^U = 0$ and, from Proposition 3, $C = A = E$. On the other hand, if either the demand function for q is highly income elastic or there are very few substitutes for q among the x 's so that σ_0 is close to zero, this could generate very large values of ξ and a substantial divergence between C and E .

¹⁷In deriving this result, one evaluates $\hat{m}(\mathbf{p}, \pi, u)$, $\hat{g}^q(\mathbf{p}, \pi, u)$, and $\hat{g}(\mathbf{p}, \pi, u)$ at $u = v(\mathbf{p}, q, y)$. Hence, the budget shares introduced above satisfy $\alpha \equiv \pi \hat{g}^q(\mathbf{p}, \pi, y + \pi q) / (y + \pi q) = \pi \hat{g}^q(\mathbf{p}, \pi, u) / \hat{m}(\mathbf{p}, \pi, u)$, and $\alpha_j \equiv p_j \hat{h}^j(\mathbf{p}, \pi, y + \pi q) / (y + \pi q) = p_j \hat{g}^j(\mathbf{p}, \pi, u) / \hat{m}(\mathbf{p}, \pi, u)$. In addition to the compensated own-price demand elasticity, ε , I introduce the compensated cross-price demand elasticities $\varepsilon_j \equiv \partial \ln \hat{g}^q(\mathbf{p}, \pi, u) / \partial p_j$. The homogeneity of $\hat{g}^q(\cdot)$ in (\mathbf{p}, π) implies that $\varepsilon + \sum \varepsilon_j = 0$. Under the assumption that $p_j = \theta \bar{p}_j$, $j = 1, \dots, N$, the Allen-Uzawa elasticity of substitution between q and the composite good x_0 is given by $\sigma_0 \equiv [(\partial \hat{g}^q / \partial \theta) \cdot \theta / q] / \alpha_0$ where $\alpha_0 \equiv \sum \alpha_j = 1 - \alpha$ is the expenditure share of x_0 and θ is treated as its price. Observe that $\partial \hat{g}^q / \partial \theta = \sum (\partial \hat{g}^q / \partial p_j) \cdot \bar{p}_j = \sum (\partial \hat{g}^q / \partial p_j) \cdot (p_j / \theta) = (q / \theta) \sum \varepsilon_j = -(q / \theta) \varepsilon$. Hence, $\sigma_0(1 - \alpha) = (\theta / q)(\partial \hat{g}^q / \partial \theta) = -\varepsilon$.

III. Applications

In the first application of (17), the price flexibility of income, ξ , is assumed to be a constant. In that case, as Randall and Stoll note, the bounds in Proposition 3 hold as equalities, and (for simplicity I focus on the case where $\xi \neq 1$):

$$(18a) \quad \frac{C}{y} = 1 - \left[1 - (1 - \xi) \frac{A}{y} \right]^{\frac{1}{1 - \xi}}$$

$$(18b) \quad \frac{E}{y} = \left[1 + (1 - \xi) \frac{A}{y} \right]^{\frac{1}{1 - \xi}} - 1.$$

However, before these formulas can be used to calculate C and E , one must determine how A varies with ξ .

If the price flexibility of income is to be constant, the inverse ordinary demand function must take the form

$$(18c) \quad \hat{\pi}(\mathbf{p}, q, y) = \psi(\mathbf{p}, q) y^\xi$$

where $\psi \geq 0$. Define $G(\mathbf{p}, q) \equiv \int \psi(\mathbf{p}, q) dq$; from (14):¹⁸

$$(18d) \quad A = y^\xi [G(\mathbf{p}, q^1) - G(\mathbf{p}, q^0)].$$

Substituting (18c) into (13) and integrating yields the indirect utility function that generates (18c):

$$(18e) \quad v(\mathbf{p}, q, y)$$

$$= T \left(\left[y^{1 - \xi} + (1 - \xi) G(\mathbf{p}, q) \right]^{\frac{1}{1 - \xi}}, \mathbf{p} \right)$$

where $T(\cdot)$ is some function that is homogeneous of degree zero, increasing in its first argument, and nonincreasing in its other arguments.

¹⁸In order to satisfy the negativity and homogeneity conditions, $\psi(\cdot)$ should be increasing in q and homogeneous of degree $1 - \xi$ in \mathbf{p} . It follows that $G(\cdot)$, too, is homogeneous of degree $1 - \xi$ in \mathbf{p} .

The corresponding demand function for q , $\hat{h}^q(\mathbf{p}, \pi, y)$ can be derived from (18e) by solving $\max_q [v(\mathbf{p}, q, y - \pi q)]$. In general, a closed-form solution cannot be obtained. However, implicit differentiation of the first-order condition for this maximization yields the following expression for the income elasticity of demand:

$$\eta = \frac{\xi \psi + \xi \psi^2 q y^{\xi-1}}{-q \psi_q + \xi \psi^2 q y^{\xi-1}}.$$

It follows that having a constant ξ is generally *not* consistent with having a constant η or a constant σ_0 . An exception occurs when

$$(19a) \quad \xi \psi \equiv -q \psi_q$$

in which case $\eta \equiv 1$ and, from (17), $\sigma_0 \equiv 1/\xi$ (i.e., the price flexibility of income is merely the reciprocal of the elasticity of substitution between q and the x 's). Integrating (19a) yields $\psi(\mathbf{p}, q) = K(\mathbf{p})q^{-\xi}$ for some function $K(\mathbf{p}) \geq 0$ which is homogeneous of degree $1-\xi$, and $G(\mathbf{p}, q) = K(\mathbf{p})q^{1-\xi}/(1-\xi)$. Hence,

$$(19b) \quad A/y = K(\mathbf{p})y^{\xi-1}[(q^1)^{1-\xi} - (q^0)^{1-\xi}]/(1-\xi)$$

and the formulas for C and E become

$$(19c) \quad C/y = 1 - \left\{ 1 - K(\mathbf{p})y^{\xi-1}[(q^1)^{1-\xi} - (q^0)^{1-\xi}] \right\}^{\frac{1}{1-\xi}}$$

$$(19d) \quad E/y = \left\{ 1 + K(\mathbf{p})y^{\xi-1}[(q^1)^{1-\xi} - (q^0)^{1-\xi}] \right\}^{\frac{1}{1-\xi}} - 1.$$

This model with a unitary income elasticity, η , is the only case in which ξ , η , and σ_0 can all be constant simultaneously. It can be shown to be a generalization of the CES utility model $u(\mathbf{x}, q) =$

$[\phi(\mathbf{x})^{1-\xi} + aq^{1-\xi}]^{1/(1-\xi)}$ with homogeneous aggregator function, $\phi(\cdot)$.¹⁹

Equation (19b) makes explicit the dependence of A on ξ . From (19c) and (19d), it follows that the ratio E/C is increasing in both $K(\mathbf{p})$ and ξ . Table 1 tabulates this ratio for several values of K and ξ , for cases where $q^0 = 1$ and $q^1 = 3$. Observe that a low elasticity of substitution ($\sigma_0 \approx 0.07$) can generate a fivefold difference between C and E , even when A/y is very small.²⁰ A similar divergence between C and E can be obtained with a relatively moderate elasticity of substitution ($\sigma_0 = 0.99$), provided that the change matters a lot, in the sense that C/y is large ($C/y \approx 0.8$). However, C is almost identical to E when moderate or large elasticities of substitution are combined with low values of C/y .

The second application is the case in which the inverse demand function takes the form

$$(20a) \quad \hat{\pi}(\mathbf{p}, q, y) = \psi(\mathbf{p}, q)e^{\gamma(\mathbf{p})y}$$

and the price flexibility of income is $\xi = \gamma(\mathbf{p}) \cdot y$, for some $\gamma(\cdot) \geq 0$ which is homogeneous of degree -1 in \mathbf{p} , and some $\psi(\cdot) \geq 0$ which is homogeneous of degree 1 in \mathbf{p} . Substituting (20a) into (13) and integrating yields the indirect utility function that generates (20a):

$$(20b) \quad v(\mathbf{p}, q, y) = T \left(-\frac{e^{-\gamma(\mathbf{p})y}}{\gamma(\mathbf{p})} + G(\mathbf{p}, q), \mathbf{p} \right)$$

¹⁹The difference is that the CES model generates an indirect utility function of the form

$$\bar{v}(\mathbf{p}, q, y) = [y^{1-\xi} + K(\mathbf{p})q^{1-\xi}]^{1/(1-\xi)}$$

whereas the indirect utility function associated with (19a)–(19c) is

$$v(\mathbf{p}, q, y) = T[\bar{v}(\mathbf{p}, q, y), \mathbf{p}].$$

²⁰This is the order of magnitude by which WTA exceeds WTP in some of the empirical studies summarized in table 3.2 of Cummings et al. (1986).

TABLE 1—SIMULATIONS OF WTP AND WTA FOR A GENERALIZED CES UTILITY MODEL

ξ	y	$K(p)$	σ_0	A/y	C/y	E/y	E/C
14	1	0.95	0.0714	0.073	0.05	0.259	5.175
1.01	100	1.4	0.99	1.602	0.796	4.026	5.059
0.677	100	8.1	1.481	2.414	0.991	4.975	5.003
0.677	100	0.1	1.481	0.03	0.029	0.03	1.02

where $G \equiv \int \psi(p, q) dq$, and T is some function that is homogeneous of degree zero, increasing in its first argument, and nonincreasing in the other arguments. The corresponding formula for the elasticity of substitution between q and the x 's, expressed as a function of (p, q, y) , can be shown to be

$$(20c) \quad \sigma_0 = \frac{\psi y + q \psi^2 e^{\gamma y}}{-q y \psi_q + \gamma y q \psi^2 e^{\gamma y}}$$

From (20a) and (20b) it follows that

$$(20d) \quad A = e^{\gamma(p)y} [G(p, q^1) - G(p, q^0)]$$

$$(20e) \quad C = \gamma(p)^{-1} \cdot \ln[1 + \gamma(p)A]$$

$$(20f) \quad E = -\gamma(p)^{-1} \cdot \ln[1 - \gamma(p)A].$$

(note that, when $\gamma A > 1$, $E = \infty$). The ratio E/C is clearly increasing in $\gamma(p)$ and A .

In order to proceed further, it is necessary to take a closer look at A . For this purpose, I focus on the special case of (20) in which $\gamma(p) = \gamma/p_N$, $\psi(p, q) = \delta e^{\alpha + \delta q} p_1^{1-\beta} p_N^\beta / (\beta - 1)$, and

$$(21a) \quad v(p, q, y) =$$

$$T \left(-\frac{p_N}{\gamma} e^{-\gamma y / p_N} + \frac{e^{\alpha + \delta q}}{\beta - 1} p_1^{1-\beta} p_N^\beta, p_2, p_3, \dots, p_N \right)$$

with γ and δ as positive constants and with $\beta > 1$. This implies the following log-log de-

mand function for good 1:²¹

$$(21b) \quad \ln x_1 = \ln h^1(p, q, y) \\ = \alpha - \beta \ln(p_1 / p_N) \\ + (\gamma y / p_N) + \delta q.$$

Since $\lim_{p_1 \rightarrow \infty} \partial v(p, q, y) / \partial q = 0$, good 1 is weakly complementary with q in the sense of Mäler, and C and E can be expressed in terms of the area between the compensated demand curves $g^1(p, q^0, u)$ and $g^1(p, q^1, u)$. Furthermore, in this model the quantity A corresponds to the change in the Marshallian consumer's surplus associated with good 1.

$$(21c) \quad A \equiv \int_{q^0}^{q^1} \hat{\pi}(p, q, y) dq \\ = \left(\frac{p_1}{\beta - 1} \right) [h^1(p, q^1, y) - h^1(p, q^0, y)] \\ = \int_{p_1}^{\infty} [h^1(p, q^1, y) - h^1(p, q^0, y)] dp_1.$$

Hence, the formulas for C and E become

$$(21d) \quad \frac{C}{p_N} = \frac{1}{\gamma} \ln \left\{ 1 + \left(\frac{\gamma}{\beta - 1} \right) \left(\frac{p_1}{p_N} \right) \right. \\ \left. \times [h^1(p, q^1, y) - h^1(p, q^0, y)] \right\}$$

$$(21e) \quad \frac{E}{p_N} = \frac{1}{\gamma} \ln \left\{ 1 - \left(\frac{\gamma}{\beta - 1} \right) \left(\frac{p_1}{p_N} \right) \right. \\ \left. \times [h^1(p, q^1, y) - h^1(p, q^0, y)] \right\}.$$

²¹It follows that, in this model, the income elasticity of demand for good 1 is equal to γy , the price flexibility of income.

TABLE 2—SIMULATIONS OF WTP AND WTA FOR A LOG-LOG UTILITY MODEL

ξ	α	δ	γ	A/y	C/y	E/y	E/C
14	-13.58	0.2	0.14	0.0695	0.0486	0.259	5.334
1.01	1.42	0.3	0.0101	0.959	0.6704	3.414	5.092
0.677	2.151	0.3	0.00677	1.427	0.9987	5.004	5.011
0.677	2.28	0.13	0.00677	0.039	0.0385	0.0396	1.027

These are tabulated in Table 2 for several values of α , γ , and δ for the case in which $p_N = 1$, $p_1 = 1.5$, $\beta = 1.125$, $y = 100$, $q^0 = 1$, and $q^1 = 3$.²² The simulations confirm that $\xi = \gamma y$ and A are the key determinants of the ratio E/C . When either ξ or A is large, then $E \gg C$; when ξ and A are both small, then $E \approx C$.

This example is a striking illustration of the power of Proposition 3. From mere inspection of the ordinary demand function for x_1 in (21b) it is hardly obvious that the term $\xi = \gamma y$ should be a key determinant of the relationship between WTP and WTA for a change in q .²³ The example also raises another issue: the possibility that the quantity A , which forms the basis for Proposition 3, may be related to the conventional Marshallian consumer's surplus associated with a private market commodity, x_1 . Under what circumstances does this carry over to other utility models? Could it, in fact, apply to the

first example based on a generalization of the CES utility model?

By way of answer to the first question, the following lemma establishes that weak complementarity is but one of two conditions that must be satisfied if A is to be equated with a change in the Marshallian consumer's surplus:

LEMMA 1: Suppose there is a private market good, say x_1 , with the properties that (a) it is nonessential and weakly complementary with q , and (b)

$$\frac{\partial \hat{\pi}(\mathbf{p}, q, y)}{\partial p_1} = - \frac{\partial h^1(\mathbf{p}, q, y)}{\partial q}.$$

Then,

$$(22) \quad A = \int_{p_1}^{\infty} [h^1(\mathbf{p}, q^1, y) - h^1(\mathbf{p}, q^0, y)] dp_1.$$

PROOF:

Weak complementarity implies $\lim_{p_1 \rightarrow \infty} m_q(\mathbf{p}, q, u) = 0$. Nonessentialness implies $\lim_{p_1 \rightarrow \infty} m(\mathbf{p}, q, u) < \infty$. Hence, by (13), condition (a) implies $\lim_{p_1 \rightarrow \infty} \hat{\pi}(\mathbf{p}, q, y) = 0$. Accordingly, one can express $\hat{\pi}(\cdot)$ as

$$\begin{aligned} \hat{\pi}(\mathbf{p}, q, y) &= - \int_{p_1}^{\infty} \frac{\partial \pi(\mathbf{p}, q, y)}{\partial p_1} dp_1 \\ &= \int_{p_1}^{\infty} \frac{\partial h^1(\mathbf{p}, q, y)}{\partial q} dp_1 \end{aligned}$$

where the second equality follows from condition (b). Invoking the definition of A in (14) and changing the order of integration yields (22).

²²The parameter values in these simulations are chosen to satisfy the inequalities $(\beta - 1)p_N \leq \gamma p_1 h^1(\mathbf{p}, q, y) \leq \beta p_N$, which ensure that the direct utility function implied by (21) is quasi-concave in \mathbf{x} and q . If $u(\mathbf{x}, q)$ were not quasi-concave in q , the formulas in (21d) and (21e), would still be valid, but the Randall-Stoll bounds in Proposition 3 would not apply. That happens with another special case of (20) in which $\gamma(\mathbf{p}) = \gamma/p_N$ but $\psi(\mathbf{p}, q) = \delta p_N e^{\alpha - \beta(p_1/p_N) + \delta q} / \beta$. This generates an ordinary demand function for good 1 that is identical to (21b), except that $\ln(p_1/p_N)$ is replaced by (p_1/p_N) . Also, (21c)–(21e) hold for this model, except that $\beta - 1$ is replaced by β . However, the implicit utility function $u(\mathbf{x}, q)$ can be shown to be quasi-convex in q .

²³Also, it is hardly obvious that from the demand function in (21b) one can recover σ_0 , the elasticity of substitution between q and the x 's (all the x 's, not just x_1). This is obtained by substituting $\gamma(\mathbf{p}) \equiv \gamma/p_N$ and $\psi(\mathbf{p}, q) \equiv \delta e^{\alpha + \delta q} p_1^{1-\beta} p_N^\beta / (\beta - 1)$ into (20c). The corresponding formula for η can be obtained from $\eta = \sigma_0 \xi = \sigma_0 \gamma y / p_N$.

Application of Lemma 1 yields the answer to the second question:

PROPOSITION 4: *Partition the price vector as $\mathbf{p} = (p_1, \mathbf{p}_{(1)})$. Equation (22) holds if and only if $v(\mathbf{p}, q, y)$ can be expressed in the form*

$$(23) \quad v(\mathbf{p}, q, y) = T[G(\mathbf{p}, q), \mathbf{p}_{(1)}y]$$

where $\lim_{p \rightarrow \infty} G(\mathbf{p}, q) = \lim_{p_1 \rightarrow \infty} G_{p_1}(\mathbf{p}, q) = 0$.

PROOF:

Observe that the conditions on the derivatives of $G(\cdot)$ ensure that x_1 is nonessential and weakly complementary with q . The main task is to show that the functional structure in (23) is necessary and sufficient to satisfy condition (b) of Lemma 1. First use (10) and (12a), and then twice differentiate the implicit function $v(\mathbf{p}, q, y) - u = 0$ to obtain

$$\begin{aligned} \frac{\partial \hat{\pi}(\mathbf{p}, q, y)}{\partial p_1} &= -m_{qp_1}[\mathbf{p}, q, v(\mathbf{p}, q, y)] \\ &\quad - m_{qu}[\mathbf{p}, q, v(\mathbf{p}, q, y)] \cdot v_{p_1}(\mathbf{p}, q, y) \\ &= -(v_q v_{yp_1} - v_y v_{qp_1}) / v_y^2. \end{aligned}$$

Comparing this with $\partial h^1(\mathbf{p}, q, y) / \partial q = (v_{p_1} v_{qy} - v_y v_{qp_1})^2 / v_y^2$, it can be seen that condition (b) will be satisfied if and only if $v_q v_{yp_1} = v_{p_1} v_{qy}$. However, this is equivalent to requiring that (v_q / v_{p_1}) be independent of y , which in turn is equivalent to (23).

The log-log utility model in (21a) clearly satisfies the conditions of Proposition 4. The generalized CES utility model in (18) could also meet the conditions of the proposition, provided that p_1 appears only in the first argument of $T(\cdot)$.

Equation (23) expresses a restriction on the marginal rate of substitution between q and the price of a weakly complementary private-market good, p_1 (i.e., that it be independent of income). This condition was first introduced by Willig (1978) in his paper

on hedonic price adjustments for valuing marginal changes in q : his theorem 1 characterized the circumstances under which the marginal value of q equals the derivative with respect to q of the Marshallian consumer's surplus for x_1 , averaged over the number of units of the good consumed. Proposition 4 expresses a similar result using a different and more compact proof. Combining Propositions 3 and 4 provides a way to value *nonmarginal* changes in q by employing the change in Marshallian consumer's surplus to compute A and then using A to bound WTP or WTA. These two propositions, in effect, establish a new link between Willig's two seminal papers.²⁴

IV. Conclusion

A recent assessment of the state of the art of public-good valuation concludes "Received theory establishes that... WTP... should approximately equal... WTA.... In contrast with theoretical axioms which predict small differences between WTP and WTA, results from contingent valuation method applications wherein such measures are derived almost always demonstrate large differences between average WTP and WTA. To date, researchers have been unable to explain in any definitive way the persistently observed differences between WTP and WTA measures" (Cummings et al., 1986 p. 41.)²⁵ This paper

²⁴I am very grateful to a referee for pointing out the connection with Willig's theorem 1. In my notation, Willig's theorem states that (23) is equivalent to the equality $v_q(\mathbf{p}, q, y) / v_{p_1}(\mathbf{p}, q, y) = \hat{\pi}(\mathbf{p}, q, y) / h^1(\mathbf{p}, q, y)$.

²⁵Some of the debates on divergences between WTP and WTA have focused on the concept of loss-aversion, introduced in the economics literature by Daniel Kahneman and Amos Tversky (1979). This is a different phenomenon from that involved in the Randall-Stoll bounds: it concerns the disparity between the WTP to obtain a change from q^0 to $q^0 + \Delta$ (for some $\Delta > 0$) and the WTP to avoid a change from q^0 to $q^0 - \Delta$, which is not the same as the disparity between WTP and WTA for the same change from q^0 to $q^1 = q^0 + \Delta$. However, the loss/gain disparity can be analyzed using the tools developed in this paper. In a separate paper, I have identified the conditions under which it will exceed the disparity between WTP and WTA studied here.

offers an explanation by showing that the theoretical presumption of approximate equality between WTP and WTA is misconceived. This is because, for public goods, the relation between the two welfare measures depends on a substitution effect as well as an income effect. Given that the substitution elasticity appears in the denominator of (17) and that the Engel aggregation condition places some limit on the plausible magnitude of the income elasticity in the numerator, this suggests that the substitution effects could exert a far greater leverage on the relation between WTP and WTA than the income effects. Thus, large empirical divergences between WTP and WTA may be indicative not of some failure in the survey methodology but of a general perception on the part of the individuals surveyed that the private-market goods available in their choice set are, collectively, a rather imperfect substitute for the public good under consideration.

Strategic Buyers and the Social Cost of Monopoly

By TORE ELLINGSEN*

Competition for a monopoly position with known profitability is often analyzed as a rent-seeking game, in which the potential producers spend resources in order to obtain the monopoly. Because of such expenditures, the social cost of monopoly is commonly argued to equal the sum of "Harberger costs" (i.e., the deadweight loss) and "Tullock costs" (the expected sum of expenditures on rent seeking).¹ Recently, several writers have recognized that buyers do not always passively accept monopoly pricing. On the contrary, buyers often engage in costly rent-defending activities, such as persuading authorities to regulate the price and quality² of the monopolized good. This occurs not only when the product is an intermediary good sold to a few industrial buyers, but also when consumer organizations engage in legal proceedings and political lobbying on behalf of otherwise disparate and uncoordinated buyers.

At first glance, it is tempting to conclude that the social cost must be higher when the buyers act strategically than when they do not. Indeed, this is the position taken by, for example, John T. Wenders (1987 p. 457),

who claims that, if the buyers engage in costly rent-defending activities, "[T]his may lead to a parallel dissipation of consumers' surplus which is additive to the rent seekers dissipation of producers' surplus." However, there are two reasons why buyer expenditures are not simply additive to the Harberger and Tullock costs. First, when buyers are successful, the deadweight loss is reduced. Secondly, knowledge that monopoly pricing may not be feasible will reduce the producers' interest in the monopoly and hence lower their expenditures. The net impact on welfare from costly buyer activities is therefore far from obvious. The contribution of the present paper is to give precise conditions under which rent-defending activities increase (or decrease) social welfare.

The two formal models that have been proposed in the rent-seeking literature, the "lottery" model of Gordon Tullock (1980) and the "perfectly discriminating contest" model of Jack Hirshleifer and John G. Riley (1978) and Arye L. Hillman and Dov Samet (1987), differ mainly in the assumed relationship between the size of expenditures and the probability of winning the contest. In the lottery model, the probability that a given player wins is proportional to the relative size of his expenditures, whereas in the perfectly discriminating contest the player who spends most resources always wins. As pointed out by Hillman and Riley (1989), it would be desirable to have a unified framework in which the impact of expenditures on political decisions is derived, rather than assumed. In the absence of such a model, however, I have not been able to do better than to study the effect of introducing strategic buyers in each of the two polar cases.

The main conclusions of the analysis are the following. (i) Under the assumption of a perfectly discriminating contest, buyer lobbying is always strictly beneficial from a

*Centre for Applied Research, Norwegian School of Economics and Business Administration, N-5035 Bergen-Sandviken, Norway, and Economics of Industry Group, London School of Economics and Political Science, London WC2A 2AE. The work was financially supported by NORAS and NAVF. I thank John Riley for helpful comments on an earlier version of the paper and for informing me about his own related work (with Arye Hillman). Comments and suggestions from Geir Asheim, Steinar Holden, John Moore, Åsa Rosén and an anonymous referee are also gratefully acknowledged. Remaining errors are mine.

¹Of course, the conclusion hinges in the so-called "wastefulness postulate" (i.e., that the expenditures have no social value). However, all results of this paper can easily be modified to account for less socially wasteful expenditures.

²In what follows, I will assume that the quality is given exogenously. Presumably, the main conclusions would hold if quality as well as price were endogenously determined.

social point of view. (ii) In the lottery model, it is more likely to be beneficial if the monopoly profit is small, if the deadweight loss is large, and if there is a large number of potential producers. (iii) Buyer lobbying is more likely to increase welfare if it occurs after one seller is established than if it occurs at the rent-seeking stage. Indeed, a sufficient condition for costly postentry regulation battles to be socially beneficial under the assumptions of the lottery model is that there are at least three potential sellers. These main results are derived in Sections I, II, and III respectively. Section IV contains some final remarks.

I. The Perfectly Discriminating Contest

Whereas the idea that competition for rents is socially costly is an old one, it is only recently that economists have argued that the whole rent may be dissipated in the competitive process and, hence, that the full monopoly profit should be added to the Harberger costs in measuring the social cost of monopoly (see Tullock, 1967; Anne O. Krueger, 1974; Richard A. Posner, 1975). This conclusion has been supported by the specific game-theoretic formulations of Hirshleifer and Riley (1978) and Hillman and Samet (1987). Here, I first repeat the main ideas of their analyses, and then extend the model to allow for strategic buyers.

A. Inactive Buyers

It is assumed that a number of identical potential producers compete for a monopoly position. Being a monopolist, a seller will quote a price of p_m . This price is higher than the constrained surplus-maximizing price, p_r , which is here taken to be the price associated with zero profit.³ The corre-

sponding quantities are q_m and q_r , respectively. A seller's valuation of winning the contest is equal to the monopoly profit, T . The deadweight loss associated with non-competitive pricing is H . These assumptions are summarized in Figure 1.

Let there be n potential competitors for the monopoly position. The monopoly is awarded to the seller submitting the highest bid in a first-price sealed-bid auction in which both winner and the losers are committed to pay their bids. If the winning bid is not unique, a fair random device will determine the winner. For example, this can be thought of as a bribery game in which each seller is unaware of the size of the bribes made by its competitors and in which the largest bribe, if it is unique, wins with probability 1.

Clearly, there is no pure-strategy equilibrium of this game. If seller i believes that the highest competing bid is $b_j < T$, then the best reply is always to make a slightly higher bid than b_j . If on the other hand it is believed that seller j will bid $b_j = T$, the best reply is $b_i = 0$ for all i ; but then $b_j = T$ is not optimal, since the game can be won more cheaply. A similar argument establishes that no seller bids any given strictly positive amount with positive probability: Suppose that seller i submits $b_i > 0$ with positive probability. Then there will be an interval $[b_i - \varepsilon, b_i]$ on which no competitor will want to bid (because the probability of winning rises discontinuously if a bid in this interval is replaced with one that is slightly higher than b_i). Consequently, seller i can reduce b_i and still win the contest with the same probability, contradicting the assumption that the initial situation was an equilibrium. Hence, in equilibrium, active sellers must use continuous mixed strategies, apart possibly from the bid of 0 which may occur with positive probability.⁴

³This assumption is not substantial, but it simplifies the graphic illustration. If transfers are costless, marginal cost pricing is, of course, welfare-maximizing. Note that Figure 1 is drawn in such a way that it is technologically optimal to have a single seller (the average cost function is downward sloping in the relevant interval because of a fixed cost). It is also worth noting that the assumptions impose no restrictions on the relative magnitudes of T and H .

⁴The interpretation of a mixed-strategy equilibrium in terms of randomized actions is chosen for expositional ease only. As has been pointed out by several writers, a more compelling interpretation is in terms of beliefs: a mixed-strategy equilibrium then simply indicates that the players cannot predict their opponents' actions with full certainty.

FIGURE 1. PROFIT AND DEADWEIGHT LOSS ASSOCIATED WITH THE UNREGULATED MONOPOLY PRICE.

To see that the equilibrium must involve full rent dissipation (i.e., that total expected rent-seeking expenditures are exactly equal to T), it suffices to demonstrate that the expected profit for each participating seller is 0. Considering only symmetric strategies for sellers that do not bid 0 with probability 1, this is relatively straightforward. Note first that if all players bid 0 with positive probability, the expected profit has to be zero, as a small positive bid would increase the probability of winning discontinuously. Consider now a continuous mixed strategy. Since the lowest bid in the support of this strategy wins with probability 0, the expected profit must be 0 for all bids in the support of this strategy.

Having established that none of the participants expects a strictly positive gain from rent seeking, I arrive at the conclusion that the rent is fully dissipated: the expected sum of rent-seeking expenditures is equal to the monopoly profit. Consequently, the total social cost of monopoly with inactive buyers is $T + H$.

B. Rent-Defending Buyers

What will happen if the buyers refuse passively to accept monopoly pricing in the industry? Suppose buyers are price takers after a certain point in time but they can influence events before this point by taking costly strategic actions. These actions are typically taken to convince some authority to impose a price ceiling or to win direct control over the monopoly supply. I follow Wenders's (1987) example in assuming that, if successful, the buyers will implement the (constrained) surplus-maximizing price p_r .

In this section, the buyer organization is supposed to be strategically symmetric to a potential seller, in that all players take simultaneous moves to gain control over the monopoly. A different and perhaps more realistic assumption is made in Section III.

Whatever actual rent-defending action the buyers take, I will assume that their effectiveness in the contest is the same as that of a single producer. Consequently, the buyers will win the contest if and only if their

outlay is greater than that of the highest-bidding seller. This assumption can of course be relaxed to allow for varying degrees of buyer friendliness by the authorities.

If, as assumed here, all buyers are members of the organization, the value to the organization of winning the contest is equal to the gain in consumers' surplus, $H + T$ (see Ellingsen [1990] for a treatment of the case in which some buyers free ride on the lobbying organization). Note therefore that, in the absence of internal problems, the buyers have a higher valuation of the "prize" than does any of the individual sellers.

Again it is straightforward to check that there is no pure-strategy equilibrium. In particular, it is not an equilibrium to have buyers undertake an expenditure of T , thus securing themselves a gain of H . The reason is that, if the sellers knew that they would have to spend more than T to win, they would all bid 0; but if the sellers bid 0, it is not rational for the buyers to bid as much as T .

In exactly the same way as before, discontinuities of the strategies at other points than $b = 0$ can be ruled out, implying that the equilibrium payoff of sellers is 0. The lower bound of the equilibrium support must also be 0, since the lowest bid is certain not to win (a higher lower bound would imply a negative payoff). Another useful observation is that it never pays for the buyers to bid more than the upper bound of the support of the sellers' mixed strategy (the contest could then be won more cheaply). Furthermore, this upper bound must be equal to T ; a lower upper bound would mean that a seller could earn a positive profit by deviating. From this, it follows that the buyers' equilibrium payoff is H . This is what they earn when bidding T , winning the contest with probability 1, and hence this must be the expected payoff associated with all other bids supporting their mixed strategy.

Now it is easy to see that buyer participation is beneficial. Staying out, the buyers had a payoff of 0. When they participate, they get a payoff of H . In equilibrium, the sellers' payoff is not influenced by the buyers' participation decision. Thus, the social

cost, C , is reduced from $T + H$ to T (i.e., by the full Harberger loss).

For completeness, I give a brief algebraic check on the result. Let $G_S(b)$ be the probability that a particular seller bids less than or equal to b , and define the corresponding probability for the buyers as $G_B(b)$. Suppose that m of the n sellers decide to participate. I consider only equilibria in which the participating sellers behave symmetrically. If the above analysis is correct, the payoff to one of these sellers can then be written as

$$(1) \quad U_S(b) = TG_B(b)[G_S(b)]^{m-1} - b = 0 \\ \text{all } b \in [0, T]$$

and similarly, the buyers' payoff is

$$(2) \quad U_B(b) = (T + H)[G_S(b)]^m - b = H \\ \text{all } b \in [0, T].$$

Solving these two equations for G_S and G_B gives the equilibrium mixed strategies for sellers and buyers, respectively. By construction, all bids in the interval $[0, T]$ give a payoff of 0 to sellers and a payoff of H to buyers. The analysis is completed by checking that no deviation to bids outside the interval yields a higher payoff to any participant. The result is summarized as the following proposition.

PROPOSITION 1: (i) *In the perfectly discriminating contest, there exists a set of n (types of) equilibria, each in which $0 \leq k \leq n - 1$ sellers bid 0 with probability 1, and the remaining $m = n - k$ sellers bid according to the strategy*

$$G_S(b) = \left[\frac{H + b}{T + H} \right]^{1/m}, \quad \text{all } b \in [0, T]$$

and the buyers bid according to

$$G_B(b) = \frac{b}{T} \left[\frac{H + b}{T + H} \right]^{(1-m)/m} \\ \text{all } b \in [0, T].$$

Furthermore, $G_S(b) = G_B(b) = 1$ for all $b > T$. (ii) In this equilibrium, sellers' payoff is 0, buyers' payoff is H , and the total social cost is T , which is less than with inactive buyers.

II. The Lottery Model

The assumption that the biggest spender wins the contest with probability 1 does not seem realistic. An alternative assumption is that the probability of winning is increasing in own expenditure but that the highest bid does not win with certainty.

A model of this kind is proposed by Tullock (1980) and analyzed in detail by Hillman and Riley (1989), the latter paper containing many of the preliminary results derived below. Perhaps surprisingly, the uncertain impact of expenditures affects some of the main conclusions of the previous section.

Below, I will analyze the simplest version of the Tullock model. Here, the probability that participant i will win, P_i , can be written as

$$(3) \quad P_i(b_i) = b_i / \sum_{j=1}^{n+1} b_j$$

where $n+1$ is the number of players. In words, the probability of player i winning is equal to his proportion of the expenditures. Define

$$(4) \quad s_{n+1} \equiv \sum_{j=1}^{n+1} b_j.$$

The expected payoff for player i is then

$$(5) \quad U_i(b_i) = \frac{b_i v_i}{s_{n+1}} - b_i$$

where v_i is player i 's valuation. Since player i 's payoff is no longer discontinuous in the point where b_i is equal to the highest opposing bid, I can now look for an equilibrium in pure strategies. The first-order conditions are easily derived and require that,

if positive, player i 's expenditures are

$$(6) \quad b_i = \frac{s_{n+1} v_i - s_{n+1}^2}{v_i}$$

(remember that s_{n+1} is a function of b_i). It can also be checked that $U_i(\cdot)$ is concave in b_i , so that (6) describes an interior maximum. Assuming that it is profitable to participate for everyone (as it will be), one gets an expression for total expenditures by summing over i in (6):

$$(7) \quad s_{n+1} = \sum_{i=1}^{n+1} \frac{s_{n+1} v_i - s_{n+1}^2}{v_i}$$

and after some trivial manipulations

$$(8) \quad s_{n+1} = \left[\frac{n}{n+1} \right] a_{n+1}$$

where a_{n+1} is defined as

$$(9) \quad a_{n+1} \equiv (n+1) / \sum_{i=1}^{n+1} \frac{1}{v_i}$$

which is the harmonic mean of the players' valuations. Inserting the actual valuations, T for the sellers and $T+H$ for the buyer organization, into (8) one gets

$$(10) \quad s_{n+1} = \left[\frac{n(T+H)}{n(T+H)+T} \right] T.$$

This equation summarizes the relation between rent-seeking expenditures, s_{n+1} , and the number of contesting sellers, n . The rent-seeking expenditures are monotonically increasing in n , never less than half of T , and never exceeding T . Only in the limit, as the number of potential monopolists goes to infinity, is there full rent dissipation. This means that each of the participants has a positive payoff, validating the previous claim that participation is privately profitable [the

local maximum found in eq. (6) is also global].

To determine the social cost, the expected deadweight loss must be added to expected expenditures. The probability that the buyers will win (and that the deadweight loss is 0) is denoted P_B . Similarly, P_S denotes the probability that any given seller will win. Using (8) and (6), equation (3) can then be rewritten as

$$\begin{aligned} (3') \quad P_B &= \frac{n(v_B - v_S) + v_S}{nv_B + v_S} \\ &= \frac{nH + T}{n(T + H) + T} \\ P_S &= \frac{v_S}{nv_B + v_S} = \frac{T}{n(T + H) + T} \end{aligned}$$

Of course, $P_B + nP_S = 1$. Now, let s_n denote the expenditures of the n sellers when buyers are passive, and let a_n be defined accordingly. (Clearly, $a_n = T$.) The net increase in social cost arising from buyer participation is then

$$(11) \quad \Delta C = s_{n+1} - s_n - P_B H.$$

The expression for s_n and s_{n+1} are derived in (8), and P_B is described in (3'). It is therefore straightforward to prove the following.

PROPOSITION 2: *Buyer participation reduces the social cost if and only if $H > T/n$.*

Here, I give the crucial steps of the derivation. From (11), (8), (9), and (3')

$$\begin{aligned} (11') \quad \Delta C &= \frac{n(v_B - v_S) + v_S}{n(nv_B + v_S)} v_S \\ &\quad - \frac{n(v_B - v_S) + v_S}{nv_B + v_S} H. \end{aligned}$$

Inserting $v_B = T + H$ and $v_S = T$, it follows directly that

$$\Delta C < 0 \Leftrightarrow H > T/n.$$

Proposition 2 is rather intuitive. First, when the consumers' surplus is large relative to the profit, the social gain from a buyer victory tends to outweigh the social loss implied by the extra expenditures. Second, when the number of competitors is large, the rent is already almost dissipated by the sellers [see (8)]. Thus, the difference $s_{n+1} - s_n$ is small when n is large. On the other hand, the probability that the buyers will win (and that the efficiency loss is avoided) is always greater than $H/(T + H)$, as can be seen from (3'). Essentially, when n is large, the buyers' expenditures replace, rather than add to, the sellers' expenditures, and the positive probability of eliminating the Harberger costs is the only significant welfare effect.

This result contrasts with that of the previous section in that buyer participation may or may not be socially desirable. The reason is that the degree of rent dissipation in the lottery model depends on the number of competitors. Therefore, contrary to what happened in the perfectly discriminating contest, buyer lobbying strictly reduces the expected payoff for the potential producers. Personally, I find the similarity of the two results more interesting than their differences: expensive buyer lobbying may well increase welfare.

III. More Realistic Timing

So far, I have maintained the assumption that the buyers must compete with all potential sellers in order to win the rent-seeking game. However, in most cases, buyers launch their campaigns for regulation toward existing monopolies, rather than potential ones. Thus, a seller can enter without having to fight the buyers but may face regulation pressure thereafter. Of course, the threat of being regulated influences the desirability of the monopoly and, consequently, the rent-seeking expenditures.

Having established the formal apparatus, it is relatively easy to handle this form of strategic asymmetry. Suppose that the game has two stages: at the first, potential sellers compete for the monopoly position, and at the second, the winner fights the buyer

lobby. I am interested in finding the subgame perfect equilibrium of this two-stage game. Clearly, the second-stage competition is already adequately modeled; one can just set $n = 1$ in the models of Sections I-B and II. The equilibrium strategies of the first stage are then found by letting the sellers compete for the second-stage payoff of the monopolist.

The solution to the two-stage perfectly discriminating contest is particularly easy to find.

PROPOSITION 3: (i) *In the two-stage perfectly discriminating contest there are no rent-seeking expenditures at the first stage. The equilibrium of the second stage is that described in Proposition 1, with $n = 1$.* (ii) *The social cost is T .*

As the expected profit for the monopolist is 0 (Proposition 1, with $n = 1$), no seller is going to spend resources at stage 1, and the monopolist is picked at random. Since all expenditures are made at the second stage, the social cost is the same as with simultaneous moves (i.e., T).

The two-stage version of the lottery model is slightly more difficult to solve. Remember that the social cost consists of three elements: the expenditures incurred at the second stage [found from (10), with $n = 1$], the expenditures incurred at the first stage, and the expected efficiency loss.

The expected second-stage payoff for a seller who has won at the first stage and entered as a monopolist is

$$(12) \quad G \equiv P_S T - b_S.$$

From (3'), when a single seller fights the buyer, $P_S = T/(2T + H)$. The seller's expenditure is found by inserting the expression for total expenditures [eq. (10)], with $n = 1$, into (6). This yields

$$b_S = \frac{n(T + H)T^2}{[n(T + H) + T]^2}$$

and it follows that

$$(12') \quad G = \frac{T^3}{(2T + H)^2}.$$

Obviously, G is the prize for which the sellers will compete at stage 1. From equation (8), the expected expenditures at the first stage can be expressed as $(n - 1)G/n$. As before, the social cost when buyers remain inactive is $(n - 1)T/n + H$. Thus, buyer participation is beneficial if and only if

$$\begin{aligned} \left(\frac{n-1}{n}\right)T + H &> \left(\frac{n-1}{n}\right)\frac{T^3}{(2T+H)^2} \\ &+ \frac{T(T+H)}{2T+H} \\ &+ \left(\frac{T}{2T+H}\right)H. \end{aligned}$$

It is a matter of fairly straightforward manipulations to rewrite this condition as

$$(13) \quad \frac{(T + H)[(2n - 1)HT + (n - 3)T^2 + nH^2]}{n(2T + H)^2} > 0.$$

This yields the following proposition.

PROPOSITION 4: *In the two-stage version of the lottery model, two (different) sufficient conditions for buyer participation to be beneficial are (i) $n \geq 3$ and (ii) $n = 2$ and $H > (\sqrt{17} - 3)T/4 \approx T/3.56$.*

Condition (i) is seen directly from (13), whereas condition (ii) amounts to finding the roots of the equation: $2H^2 + 3HT - T^2 = 0$.

Proposition 4 is quite striking. A sufficient condition for buyer participation to reduce social cost is that there are at least three sellers competing for the monopoly position. Even with only two sellers, the

condition is considerably weaker ($H > T/3.56$) than under the assumption of simultaneous moves ($H > T/2$). Thus, the two-stage formulation lends further support to the claim that buyer lobbying tends to increase welfare.

IV. Final Remarks

The analysis points out three effects of buyer participation in rent-seeking games on the social cost of monopoly: the direct and detrimental effect of one extra player's expenditures, the indirect effect on opponents' expenditures, and the saved consumers' surplus.

In this paper, I have presented conditions under which expensive buyer lobbying is socially beneficial. Overall, these conditions are weak. When the highest bidder certainly wins, voluntary buyer spending is always beneficial. If the impact of spending is uncertain, the impact on welfare of costly buyer activities is ambiguous,⁵ but when buyers only need to fight an incumbent monopolist, lobbying is very likely to be beneficial.

In conclusion, I will briefly relate the above results to the work of other authors. The debt to the work of Hillman and Riley (1989) has already been acknowledged. Their general analysis of contests with asymmetric valuations is ideally suited for tackling the questions addressed here. Pointing out that asymmetric valuations will

lead to smaller expenditures in the perfectly discriminating contest, these authors anticipated the message of my Proposition 1. A similar result is also obtained by Wing Suen (1989).

To my knowledge, the first systematic attempt to highlight the role of strategic buyers in rent seeking is Barry Baysinger and Robert D. Tollison (1980; see also Tollison [1982]). One of their claims is that, when the impact of expenditures is uncertain, the total social cost of monopoly may exceed the sum of deadweight loss and monopoly profit. It should be clear from the above analysis that this is impossible. Essentially, the authors overlook the elementary fact that when expenditures are voluntary, their sum cannot exceed the prize: the buyers can earn at least the consumers' surplus associated with monopoly pricing; the sellers can secure themselves 0. They cannot jointly earn less than this in equilibrium. Hence, expected social cost cannot be larger than $T + H$. More recently, Wenders (1987) has also argued that costly rent-defending activities would unambiguously increase the social cost. Not using game-theoretic tools, he fails to recognize the effect of buyer expenditures on the behavior of other participants.

Finally, the results obtained here can be compared to those of Elie Applebaum and Eliakim Katz (1986). They analyze a model in which a number of interest groups compete for a transfer which is to be collected from the losers. They demonstrate that the participants spend more resources in this environment than if the amount of transfer had first been collected and only then contested. They draw the conclusion that costs incurred to avoid transfers tend to increase the total social cost of transfer seeking. However, this result stems simply from the fact that more is at stake for each participant in the former case than in the latter. The present paper shows that, if there is costly competition for a transfer from some *predesignated* group and there is some loss associated with the transfer, society will often gain if this group spends resources in order to avoid the transfer altogether.

⁵However, it should be mentioned that this ambiguity need not be an inherent feature of all models in which the impact of expenditures is uncertain. The lottery model exhibits some dubious properties. Particularly, entry of a new competitor never induces exit of any of the already participating sellers. In any model in which entry of buyers into the game induces exit of some seller(s), buyer participation seems likely to be beneficial. Hillman and Riley (1989) have argued that Tullock's stochastic specification, as represented by equation (3), is not founded upon any basic principle of how the uncertainty of a dollar's impact should vary with the total amount of money spent by the agent. They also present an example in which the relationship between bids and the probability of winning is derived rather than assumed. In that case, the number of participants in equilibrium is limited.

APPENDIX

Strategic Buyers and the Social Cost of Monopoly: Some Derivations

i) The manipulation leading from (7) to (8) is as follows:

$$s_{n+1} = \sum_{i=1}^{n+1} \frac{s_{n+1}v_i - s_{n+1}^2}{v_i}$$

$$1 = \sum_{i=1}^{n+1} \left[1 - \frac{s_{n+1}}{v_i} \right]$$

$$1 = n+1 - s_{n+1} \sum_{i=1}^{n+1} \frac{1}{v_i}$$

$$s_{n+1} = \frac{n}{\sum_{i=1}^{n+1} \frac{1}{v_i}}$$

which completes the demonstration [substitute the definition of a_{n+1} in (8)].

ii) From the above expression, it is also easy to derive (10):

$$\begin{aligned} s_{n+1} &= \frac{n}{\frac{n}{v_S} + \frac{1}{v_B}} = \frac{nv_B v_S}{nv_B + v_S} \\ &= \left(\frac{n(T+H)}{n(T+H)+T} \right) T \end{aligned}$$

iii) The derivation of (3'):

$$\begin{aligned} P_i &= \frac{b_i}{s_{n+1}} = \frac{\frac{s_{n+1}(v_i - s_{n+1})}{v_i}}{s_{n+1}} \\ &= \frac{v_i - s_{n+1}}{v_i} \end{aligned}$$

and thus,

$$\begin{aligned} P_B &= \frac{T+H - \left(\frac{n(T+H)}{n(T+H)+T} \right) T}{T+H} \\ &= 1 - \frac{nT}{n(T+H)+T} \\ &= \frac{T+nH}{n(T+H)+T} \\ P_S &= \frac{T - \left(\frac{n(T+H)}{n(T+H)+T} \right) T}{T} \\ &= 1 - \frac{n(T+H)}{n(T+H)+T} \\ &= \frac{T}{n(T+H)+T} \end{aligned}$$

iv) The omitted step in the proof of Proposition 2 is from (11) to (11'). Here, I find the expression for $s_{n+1} - s_n$:

$$\begin{aligned} \frac{n}{\frac{n}{v_S} + \frac{1}{v_B}} - \frac{n-1}{\frac{n-1}{v_S}} &= \frac{\frac{n}{v_S}}{\left[\frac{n}{v_S} + \frac{1}{v_B} \right] \frac{n}{v_S}} \\ &\quad - \frac{(n-1) \left[\frac{n}{v_S} + \frac{1}{v_B} \right]}{\left[\frac{n}{v_S} + \frac{1}{v_B} \right] \frac{n}{v_S}} \\ &= \frac{\frac{n}{v_S} - \frac{n-1}{v_B}}{\left[\frac{n}{v_S} + \frac{1}{v_B} \right] \frac{n}{v_S}} \\ &= \frac{nv_B - (n-1)v_S}{n \left[\frac{nv_B}{v_S} + 1 \right]} \\ &= \frac{n(v_B - v_S) + v_S}{n(nv_B + v_S)} v_S \end{aligned}$$

which is the first part of equation (11').

v) In the derivation of (13), the only trick is to show that

$$\begin{aligned} & (n-3)T^3 + (3n-4)HT^2 \\ & + (3n-1)H^2T + nH^3 \\ & = (T+H)[nH(T+H) + nHT \\ & - T(T+H) - 2T^2 + nT^2]. \end{aligned}$$

Increasing the Profits of a Subset of Firms in Oligopoly Models with Strategic Substitutes

By GÉRARD GAUDET AND STEPHEN W. SALANT*

Consider an industry composed of N firms in a symmetric equilibrium. Designate a subset of S ($\leq N$) firms and marginally reduce the strategic variables of the firms in the subset. If the remaining firms simultaneously make the best reply to this exogenous displacement, under what circumstances will profits of the firms in the designated subset increase?

We show that, in the case of Cournot competition among producers of perfect substitutes, a marginal contraction is strictly beneficial (strictly harmful) if and only if the number of firms in the designated subset exceeds the "adjusted" number of firms outside it by strictly more (strictly less) than one. The adjustment factor is unity when cost and demand functions are linear but, more generally, depends on the convexity of the cost and demand curves. Thus, a marginal contraction of two firms in a triopoly has no effect on the profits of firms in the subset if cost and demand functions are linear; if instead cost is linear but the inverse demand function is strictly concave (strictly convex), a marginal contraction will strictly decrease (strictly increase) profits. The analysis is extended to the effects of *nonmarginal* exogenous changes in the outputs of the constrained firms. This extension has implications for the relationship of Stackelberg (sequential move) and Nash (simultaneous move) equilibria.

Our analysis has broad application. To illustrate, we show that it unifies results in the literature on export subsidies, horizontal mergers, and strikes.

The paper is organized as follows. In Section I, our comparative-static result is derived. In Section II, we present a wide range of applications. In the conclusion and the Appendix we generalize our analysis to other situations involving strategic substitutes.

I. The Effect of an Exogenous Output Contraction

A. Marginal Changes

Consider an industry composed of N firms producing a homogeneous good with identical cost functions. Denote the inverse market demand by $p(Q)$. It is assumed that there is a $Q^0 > 0$ such that $p(Q) > 0$ for $Q < Q^0$ and $p(Q) = 0$ for $Q \geq Q^0$ and that $p(Q)$ is twice continuously differentiable with $p'(Q) < 0$ for $Q < Q^0$. The typical firm's cost of production is $C(q)$, with $C(q) > 0$ if $q > 0$ and $C(0) = 0$. It is assumed to possess continuous first and second derivatives, which satisfy $C' \geq 0$ and $C'' \geq 0$.

We further assume that $p'(Q) + qp''(Q) < 0$ for all $0 \leq q \leq Q \leq Q^0$. Thus, a given firm's marginal profit must fall when any rival firm increases its output. The goods are therefore strategic substitutes: each firm's best-reply function is downward sloping.¹

These assumptions insure that a unique symmetric Cournot equilibrium exists in

¹See Jeremy I. Bulow et al. (1985) for a general definition of strategic substitutes and complements. We discuss briefly the implications of our analysis for strategic complements in the concluding section and the Appendix.

pure strategies.² Now assume that this initial equilibrium is displaced. In particular, assume that each firm in a designated subset of $S \leq N$ firms is constrained to produce an exogenous amount, \bar{q} . The output of each of the unconstrained $N - S$ firms is endogenous. We denote it by q and, to emphasize its dependence on \bar{q} , sometimes write $q(\bar{q}, N, S)$.

Let firm i be a member of the constrained subset and let π^s denote the profit of this firm. It can be expressed as a function of two variables, own output and the aggregate output of the other $N - 1$ firms:

$$(1) \quad \pi^s(\bar{q}, Q_{-i}) = \bar{q}p(\bar{q} + Q_{-i}) - C(\bar{q})$$

where $Q_{-i} = (N - S)q + (S - 1)\bar{q}$ denotes the aggregate output of every firm other than i .

If $\bar{q} = q$, firm i 's output is a best reply and

$$(2) \quad \left. \frac{\partial \pi^s(\bar{q}, Q_{-i})}{\partial \bar{q}} \right|_{\bar{q}=q} = 0.$$

Totally differentiating (1) and using (2) to evaluate the derivative at $\bar{q} = q$, we obtain

$$(3) \quad \left. \frac{d\pi^s}{d\bar{q}} \right|_{\bar{q}=q} = \frac{\partial \pi^s(\bar{q}, Q_{-i})}{\partial Q_{-i}} \frac{dQ_{-i}}{d\bar{q}} = \bar{q}p' \frac{dQ_{-i}}{d\bar{q}}.$$

Since $p' < 0$, it follows that a marginal change (increase or decrease) in \bar{q} in a neighborhood of the initial equilibrium will raise the profit of any given firm in the constrained subset if and only if the equilibrium aggregate output of the $N - 1$ other firms declines as a consequence. From the definition of Q_{-i} ,

$$(4) \quad \frac{dQ_{-i}}{d\bar{q}} = (N - S) \frac{dq}{d\bar{q}} + (S - 1).$$

It follows that

$$(5) \quad \left. \frac{d\pi^s}{d\bar{q}} \right|_{\bar{q}=q} \gtrless 0 \Leftrightarrow (N - S) \frac{dq}{d\bar{q}} + (S - 1) \gtrless 0.$$

Since the goods are strategic substitutes, each of the $N - S$ unconstrained firms responds to a marginal reduction in \bar{q} by *increasing* its output ($dq/d\bar{q} < 0$). In the extreme case where $S = 1$ and $N > 1$, then $d\pi^s/d\bar{q} > 0$. A marginal contraction in \bar{q} increases the aggregate output of the firms other than i since there are no other firms *inside* the constrained subset; hence, firm i 's profits must fall. This explains why a Stackelberg leader who takes over one firm in a duopoly will instead *expand* its production. If, at the other extreme, $S = N > 1$, then $d\pi^s/d\bar{q} < 0$. In that case, a marginal contraction in the output of the S firms will cause Q_{-i} to fall since there are no firms *outside* the constrained subset; hence, the profits of firm i must rise. This explains why it is always profitable for a monopolist who takes over an industry of N independent firms to contract the production of each. In these polar cases, the qualitative results do not depend on the responsiveness of the outside firms to the exogenous contraction in the outputs of the S firms.

When $1 < S < N$, however, the *magnitude* of the response of the unconstrained firms does determine whether a marginal contraction of the outputs of the S firms increases or decreases their profits. The equilibrium output $q(\bar{q}, N, S)$ of each unconstrained firm solves the following first-order condition:

$$(6) \quad p(S\bar{q} + [N - S]q) + qp'(S\bar{q} + [N - S]q) - C'(q) = 0$$

from which we derive

$$(7) \quad \frac{dq}{d\bar{q}} = \frac{-S\alpha}{(N - S)\alpha + 1} = \frac{-S}{(N - S) + 1/\alpha} < 0$$

²For details, see Gaudet and Salant (1991b).

where

$$(8) \quad \alpha = \frac{p' + qp''}{p' - C''} > 0.$$

The larger is α , the more responsive are the unconstrained firms.³ The magnitude of α in turn depends upon the slope of the marginal cost function of each unconstrained firm as well as the curvature of the demand function. This is intuitively plausible: with linear demand, for example, an increase in the slope of the marginal cost curve (C'') of each unconstrained firm reduces α and hence reduces responsiveness to changes in \bar{q} .

Substituting the expression for this response from (7) into (5), we get

$$(9) \quad \left. \frac{d\pi^s}{d\bar{q}} \right|_{\bar{q}=q} \leq 0 \Leftrightarrow S-1 \geq \alpha(N-S).$$

In the case where $\alpha = 1$ (for example, when $C'' = p'' = 0$) condition (9) says that the firms in the subset will strictly gain from an exogenously induced marginal contraction of their output if and only if they outnumber the firms outside the subset by more than one. Refer to the term $\alpha(N-S)$ as the "adjusted" number of firms outside the subset. Then, more generally, a marginal output contraction is profitable for the firms in the subset if and only if they exceed the adjusted number of firms outside the subset by more than one.⁴

B. Nonmarginal Changes

A geometric illustration of our results will be helpful in analyzing nonmarginal changes. For any exogenous \bar{q} , each uncon-

strained firm will produce $q(\bar{q}, N, S)$, as defined by (6). We represent this in Figure 1 as a downward-sloping locus in (\bar{q}, q) -space with slope given by (7).⁵ For simplicity, we have drawn it as a line. The unconstrained symmetric equilibrium occurs where the upward-sloping 45-degree line intersects this downward-sloping locus.

Denote the aggregate profits of the S firms in the subset by Π^s :

$$(10) \quad \Pi^s(\bar{q}, q) = S[\bar{q}p(S\bar{q} + [N-S]q) - C(\bar{q})].$$

The slope of the "isoprofit curve" through the unconstrained equilibrium point ($\bar{q} = q$) is therefore

$$(11) \quad \left. \frac{d\bar{q}}{dq} \right|_{\bar{q}=q} = -\frac{S-1}{N-S}.$$

Notice that at $\bar{q} = q$ this slope depends only on the numbers (N, S) and not on the curvature of the demand or cost curves. Moreover, it is negative, except in the over-studied special case in which $S = 1$.⁶ Since a reduction in q with \bar{q} fixed would raise price and increase the profits of the S firms, points below this isoprofit curve represent higher profits to the S firms. We will assume that, for any finite N , $\Pi^s(\bar{q}, q(\bar{q}, N, S))$ is a strictly quasi-concave function of \bar{q} .⁷ Our assumptions are jointly sufficient to insure that each isoprofit line cuts the downward-sloping locus at most twice and that $\Pi^s(\bar{q}, q(\bar{q}, N, S))$ has a unique maximum as a function of \bar{q} .

³Farrell and Shapiro (1990) make use of the same expression as α in their analysis of the welfare effects of horizontal mergers.

⁴Notice that α and hence (9) depend on the curvature of the cost functions of the unconstrained firms but not of the constrained firms. Thus, as pointed out by an anonymous referee, the assumption that the constrained and unconstrained firms are identical is not necessary.

⁵Equation (11) can be readily interpreted. If each of the S firms contracts by one unit, then an expansion by each of the $N-S$ firms by $(S-1)/(N-S)$ units would result in a zero net expansion of the $N-1$ firms other than the designated constrained firm and hence would not change the profits of the S constrained firms.

⁶The locus will be linear for any (N, S) when the demand and cost curves are linear. In the most familiar case with $S=1$ and $N=2$, the locus is the linear "reaction function" with slope $-1/2$.

⁷This assumption will be satisfied if, for example, demand is linear and marginal cost is constant. In that case $\Pi^s(\bar{q}, q(\bar{q}, N, S))$ is strictly concave in \bar{q} .

FIGURE 1. NONMARGINAL CHANGES WHEN THE ISOPROFIT CONTOUR THROUGH THE UNCONSTRAINED EQUILIBRIUM POINT IS (A) STEEPER, (B) AS STEEP, OR (C) FLATTER THAN THE DOWNWARD-SLOPING LOCUS DEFINED BY EQUATION (6).

Three possibilities can arise. The isoprofit contour through the unconstrained equilibrium point can be (A) steeper, (B) as steep, or (C) flatter than the downward-sloping locus defined by the first-order condition (6); that is,

$$(12) \quad -\frac{S-1}{N-S} \gtrless \left. \frac{dq(\bar{q}, N, S)}{d\bar{q}} \right|_{\bar{q}=q}$$

where the right-hand side is given by (7) evaluated at $\bar{q} = q$. A marginal contraction in \bar{q} will be beneficial to the S firms in case (A), neutral in case (B), and injurious in case (C). This clarifies (5) geometrically. We illustrate cases (A), (B), and (C) respectively in the three panels of Figure 1.

As we have previously shown, case (A) occurs when $S - \alpha(N - S) > 1$. In that case, a *marginal* contraction would be beneficial. However, note that there is some level of \bar{q} for which the profits of the S firms would be exactly the same as in the unconstrained equilibrium. Denote this level of \bar{q} by γ_1 . Geometrically, γ_1 is the horizontal coordinate of the point where the isoprofit contour through the unconstrained equilibrium point cuts the downward-sloping locus to the *left* of the unconstrained equilibrium point. Analytically, γ_1 is the value of $\gamma < q^*$ that solves⁸

$$(13) \quad p(S\gamma + [N - S]q(\gamma, N, S))\gamma - C(\gamma) \\ = p^*q^* - C(q^*)$$

where p^* and q^* are the price and outputs in the unconstrained Cournot equilibrium. Reducing the output of each constrained firm below the critical level γ_1 will lower their profits relative to the unconstrained equilibrium.

Similarly, case (C) occurs when $S - \alpha(N - S) < 1$. In that case, a *marginal* expansion would be beneficial. However, if the constrained firms were compelled to expand their outputs to γ_2 , their profits would be

⁸Our assumptions insure that (13) yields a unique value for γ .

reduced to the level in the unconstrained equilibrium. Geometrically, γ_2 is the horizontal coordinate of the point where the isoprofit contour through the unconstrained equilibrium point cuts the downward-sloping locus to the *right* of the unconstrained equilibrium point. Analytically, γ_2 is the value of $\gamma > q^*$ that solves equation (13). Increasing the output of each constrained firm above γ_2 will lower profits below their initial level.

II. Applications

The comparative-static results we have been investigating have many applications. Consider first the effect of a labor strike on the profits of the struck firms.⁹ It is often taken for granted that a struck firm must be harmed by the forced reduction in its output.¹⁰ However, our analysis delineates circumstances in which, under an oligopolistic market structure, each targeted firm will in fact benefit from a strike.¹¹ The 1979 strike against selected lettuce producers in the Imperial Valley of California appears to have illustrated this perverse result.¹²

Our results imply that a marginal strike is strictly beneficial to each struck firm if and only if the number of struck firms exceeds the (adjusted) number of nonstruck firms by more than one. Under the same circumstances, a nonmarginal strike will also be beneficial as long as the output of each

struck firm is not forced below the critical level, $\gamma_1 < q^*$, defined in (13).

As a second application, consider the rationale for subsidizing the exports of domestic firms discussed recently by James A. Brander and Barbara J. Spencer (1985).¹³ They consider a model in which Cournot duopolists, one in each country, export to consumers in a third country. They show that imposition of a marginal subsidy, in the neighborhood of free trade equilibrium, will always increase the profit of the domestic firm *net of the subsidy*.¹⁴ These results rely again on the comparative-static properties of the Cournot model derived in Section I. Our analysis makes clear that the Brander and Spencer result is a special case: regardless of the curvatures of the cost and demand curves, if there is only one domestic firm in the subset ($S = 1$) and one or more foreign firms ($N - S \geq 1$), then a marginal expansion of the output of the firm in the subset in the neighborhood of Cournot equilibrium must increase its profits. This clearly follows from (9). In an N -firm oligopoly, however, the domestic attractiveness of the subsidy will depend on the number of domestic firms.¹⁵ In fact, the optimal policy may instead be a tax.

⁹A more timely example might be the effects on the profits of a subset of the world's coca growers if the "war on drugs" succeeds in slightly reducing their production.

¹⁰A strike might not only reduce output but might in addition increase the cost of producing that reduced output. We ignore this additional effect but note that, even in its presence, each targeted firm might still benefit from the strike. A similar point can be made about the war on drugs discussed in the previous footnote.

¹¹Under a competitive market structure, each targeted firm will in fact always benefit from a "marginal" strike, no matter how small a proportion of the firms are targeted. For a formal discussion of the comparative-static results in the competitive case, see Gaudet and Salant (1989).

¹²See Colin A. Carter et al. (1981) for an empirical analysis of the effects of this strike.

¹³The issues raised by Brander and Spencer's model are not confined to the international arena. To the extent that any government, be it city, state, or national, wishes to increase the profits of producers, its concern is restricted to the producers within its own jurisdiction; but those producers constitute only a subset of the industry when some firms lie beyond that jurisdiction. For example, California subsidizes the water used by its farmers. While this affects profits of farms in other states, it is the profits of in-state farms that the California government is concerned to influence.

¹⁴Jonathan Eaton and Gene M. Grossman (1986) also consider Bertrand competition in their analysis of optimal trade policy under oligopoly. They show that, whether the duopolists compete in price or quantity, an export tax (rather than subsidy) is optimal if the goods are strategic complements (upward-sloping reaction functions) but not complements in demand. The export subsidy is optimal if the goods are strategic substitutes. The extension of our analysis to strategic complementarity and demand complementarity, discussed in the concluding section and the Appendix, will clarify the intuition behind this result.

¹⁵On this point, see also Avinash Dixit (1984) and Salant (1984). Referring to these papers, Brander and

If the number of domestic firms exceeds the (adjusted) number of foreign firms by more than one, the output of the S home firms in the unconstrained (*laissez-faire*) Cournot equilibrium is larger than the output of each if they were operated by a Stackelberg leader ($q^* > \bar{q}^K$) as is illustrated in Figure 1A. A tax induces a contraction in their outputs and therefore increases their profit (inclusive of the rebated taxes), provided the output of each firm is not reduced below γ_1 . An export subsidy of any magnitude, on the other hand, would adversely affect the home country.

If instead the number of domestic firms exceeds the (adjusted) number of foreign firms by less than one, the output of the S firms in the unconstrained Cournot equilibrium is smaller than if they were operated by a Stackelberg leader ($q^* < \bar{q}^K$), as is illustrated in Figure 1C. A subsidy induces an expansion in their outputs and therefore increases their profits (net of the subsidy payments) provided it does not induce output of each home firm to exceed γ_2 . In this case, of course, the trade policy optimal for the S firms is an export subsidy sufficient to induce each firm to produce \bar{q}^K units.¹⁶ An export tax of any magnitude would, on the other hand, adversely affect the home country.

Suppose finally that the subset now represents firms that are part of a merger or, equivalently, members of a cartel (with perfect enforcement). In general, merging or forming a cartel will cause price to rise, aggregate output to fall, the outputs and profits of the $N - S$ outside firms to rise, and the outputs of the merged entity to fall. Salant et al. (1983) and others have pointed out, however, that the profits of the merged entity (or cartel) may fall. A merger would, of course, increase profits if output of the $N - S$ outside firms remained unchanged.

However, their output will not remain unchanged; it will increase. As a result of outsider expansion, merging or cartelizing some subset of firms exogenously may be disadvantageous; if the merger decision were endogenized, such mergers would presumably not occur.

This "losses from merger" result is yet another consequence of properties of the Cournot model investigated in Section I. The premerger equilibrium is simply the "unconstrained Cournot equilibrium" of that section. As for the postmerger equilibrium, as long as $C'' \geq 0$, each of the S firms party to the merger will produce equal outputs, and the other $N - S$ firms will best reply.

Whenever the number of firms in a merger exceeds the (adjusted) number of outside firms by less than one, the output in the initial unconstrained Cournot equilibrium of each of the S firms that will merge is smaller than the output a Stackelberg leader would choose, as is illustrated in Figure 1C. Since a merger will cause each of the S firms to reduce its output, their profits must fall.

Whenever the number of firms in a merger exceeds the (adjusted) number of outside firms by more than one, a marginal contraction of output is profitable. However, a merger results in a *nonmarginal* contraction in output, and this may or may not be profitable. This case is illustrated in Figure 1A. Let q_m denote the postmerger equilibrium output of each merged firm. If $q_m < \gamma_1$, the merger will cause a loss.¹⁷ If, on the other hand, $\gamma_1 < q_m < q^*$, the merger will cause a gain.

To emphasize the relationship of the seemingly dissimilar literatures on export

Spencer (1985 p. 85 [footnote 6]) acknowledge that "adding more domestic firms weakens the case for domestic subsidies." Indeed, it can easily destroy the case.

¹⁶When the domestic sector consists of a single firm ($S = 1, N \geq 2$), this case must necessarily arise.

¹⁷A particularly striking example has been worked out by Ulrich Zachau (1987). With quadratic costs and proportional demand ($p = v/Q$), for any N and any $1 < S < N$, a merger causes a loss; the only merger that is profitable is merger to monopoly. In this example, whenever a marginal contraction would be profitable, the merger results in a nonmarginal contraction that is so large that $q_m < \gamma_1$, and a loss results.

subsidies and on horizontal mergers, we state the following propositions:

PROPOSITION 1: *Whenever an export subsidy would increase the profits of the home country, merging the entire export sector must cause a loss.*

PROPOSITION 2: *Whenever merging the entire export sector would cause a gain, an export subsidy must reduce the profits of the home country.*

III. Generalizations

In the previous sections, we analyzed the case of quantity competition among firms selling perfect substitutes. We showed that whether an exogenous marginal contraction of the scalar strategies of each of S firms in a subset increases or decreases their profits depends on the number of firms in the constrained subset versus the number of firms in its complement.

This result clearly does not depend on the assumption of quantity competition. For, as Hugo Sonnenschein (1968) pointed out, any result in a market where firms compete in quantity and sell perfect substitutes also holds in a market where firms compete in price and sell perfect complements.¹⁸

Indeed, even in the absence of perfect substitutes (or complements) and even when the strategic variable is neither quantity nor price, analogous results hold. As the Appendix clarifies, such results hold if and only if the interaction involves strategic substitutes.¹⁹

¹⁸One example of the latter form of competition would be independent railroads whose tracks adjoin end to end. Since customers shipping goods from one end to the other would have to pay the *sum* of the fares, this case involves price competition in perfect complements. A theoretical discussion of the profitability of partial consolidation in this example is contained in Gaudet and Salant (1991a); Christopher A. Velturo (1988) and the references he cites discuss the history of railroad consolidations in the United States.

¹⁹Carl Davidson and Raymond Deneckere (1985) implicitly illustrate the "only if" part of the assertion. They consider a model involving price competition and substitutes in demand and show that mergers never

APPENDIX

Generalization of the Comparative-Statics Result on Profits

Consider a symmetric game in which each of N players simultaneously selects a scalar strategy, a_i , $i = 1, \dots, N$, and payoffs are collected. The payoff of player i , $i = 1, \dots, N$, is given by $\pi^i(a_1, \dots, a_i, \dots, a_N)$. We assume that π^i is twice continuously differentiable. We also assume that there exists a unique pure-strategy Nash equilibrium and that it is symmetric. Denote it as $a_i = a$, $i = 1, \dots, N$.

A subset of S players has the constraint $a_i = \bar{a}$ exogenously imposed on it. Without loss of generality, we may assign the subscripts $1, 2, \dots, S$ to these players. The initial equilibrium will be displaced if and only if $\bar{a} \neq a$. We refer to the situation where $\bar{a} = a$ as the unconstrained equilibrium. Given N and S , at the new equilibrium, we will have $a_i(\bar{a})$, $i = S+1, \dots, N$, as an implicit solution to the first-order condition of the $N-S$ players outside the subset.

The effect of a marginal change in \bar{a} on the equilibrium profit of the typical firm in the subset ($i = 1, \dots, S$) is given by

$$(14) \quad \frac{d\pi^i}{d\bar{a}} = \frac{\partial \pi^i}{\partial a_i} + \sum_{\substack{j=1 \\ j \neq i}}^S \frac{\partial \pi^i}{\partial a_j} + \sum_{j=S+1}^N \frac{\partial \pi^i}{\partial a_j} \cdot \frac{da_j}{d\bar{a}}.$$

When $da_j/d\bar{a}$ is positive (negative), we have "strategic complements" (strategic substitutes). We consider the case in which $\partial \pi^i/\partial a_j$ has the same sign at the unconstrained equilibrium for all $j \neq i$, $i = 1, \dots, S$ and $da_j/d\bar{a}$ has the same sign for all $j = S+1, \dots, N$.

cause losses. Strategic complementarity—not the fact that price is the strategic variable—is responsible for this result.

When evaluated at the unconstrained equilibrium, $\partial\pi^i/\partial a_i = 0$ for all $i = 1, \dots, N$. Hence, for strategic complements, (14) implies $\text{sgn}(d\pi^i/d\bar{a}) = \text{sgn}(\partial\pi^i/\partial a_j)$ in a neighborhood of the unconstrained equilibrium, independently of N and S . On the other hand, for strategic substitutes, $\text{sgn}(d\pi^i/d\bar{a})$ clearly depends on (N, S) . For example, when $S = 1$, the first summation is zero and $\text{sgn}(d\pi^i/d\bar{a}) = -\text{sgn}(\partial\pi^i/\partial a_j)$. When $N = S$, the second summation is zero and $\text{sgn}(d\pi^i/d\bar{a}) = \text{sgn}(\partial\pi^i/\partial a_j)$.

These results are general. They include price and quantity competition as important special cases. Hence, $\partial\pi^i/\partial a_j < 0$ arises in quantity competition if the goods are substitutes in demand, and in price competition if the goods are complements in demand; $\partial\pi^i/\partial a_j > 0$ arises in quantity competition if the goods are complements, and in price competition if the goods are substitutes.

Pricing Schemes and Cournotian Equilibria

By C. D'ASPREMONT, R. DOS SANTOS FERREIRA, AND
L.-A. GÉRARD-VARET*

There are, essentially, two basic models for studying oligopolistic competition: the Cournot model, with quantity-setting firms in a market for a single homogeneous good, and the monopolistic competition model, with price-setting firms, each in a different market of a differentiated good. In both models, the analysis starts by assuming a large set of consumers who adjust in a perfectly competitive way. Only the firms are supposed to behave strategically and to privilege one strategic variable, the quantity produced or the selling price. This paper is an attempt—among others¹—to integrate the two models and to admit the interaction of the two kinds of strategic variables.

This integration will be based on a reinterpretation of Augustin Cournot's approach. In the famous chapter in which Cournot (1838) introduced his oligopoly theory, he does mention, from the start, that the selling price should "necessarily" be the same for each producer. However, he does not elaborate much on price formation, except to say that it is convenient to use the inverse demand function. One may argue that the lack of explanation for price determination in the Cournot model is analogous to the lack of one in the perfect-competition model, and a Walrasian auctioneer might be hypothetically introduced. Of

course, one difference is that the auctioneer may only act on one side of the market, the demand side. Supply is dictated to him by the firms, and so they themselves integrate into their computations the influence of their supply on the resulting market price. However, the lack of a price-adjustment theory and the idea that such a theory should be rooted on a price-adjustment process under monopoly (one firm adjusting both price and quantity), as advocated by Kenneth J. Arrow (1959) for the perfect-competition model, apply as well to the Cournot oligopoly model. To invoke the "necessity" that the producers of a homogeneous good charge the same price is not different from invoking the "impersonal forces of the market" to justify one competitive equilibrium price that all agents take as given. The argument that, out of equilibrium, producers behave as monopolists and do consider the influence of the price they charge on the (imperfectly elastic) demand they face should also be maintained. The main contrast, finally, is that this argument is still valid at equilibrium in the Cournot oligopoly model. Even there, the producers do not take the price they charge as given. Moreover, they know that, if they were charging different prices, some adjustment process would take place leading again to a single market price. Out of equilibrium, there is a discrepancy between the price they want to charge and the market price (or the average price²), and this triggers the adjustment. At equilibrium the two coincide.

In this paper, we shall not introduce a theory of price adjustment under conditions

²To quote Arrow (1959 p. 48), "However the 'price' whose movements are explained by the law must be thought of as the average price."

of imperfect competition. We shall insist instead that the result of any such theory would be different from the result of a theory of price adjustment under perfect competition: at equilibrium each firm should be fully aware of its own influence on the market price. To formalize this conclusion, we shall introduce explicitly a concept of "pricing scheme" associating with a vector of price announcements the resulting market price. It will appear that, if the pricing scheme (which is nothing else than a coordination device) is sufficiently responsive to individual price signals, then we get the Cournot equilibrium. This leads to the interpretation of a Cournot equilibrium as the coordinated optimal decisions of a set of monopolists, each facing some (imperfectly elastic) residual demand. In the original Cournot model, the same coordination is ensured by the use of the inverse demand function. Formally, pricing schemes have the same status as auctions or bidding mechanisms. They could be assimilated to what is known in industrial organization as "facilitating practices" (see Steven C. Salop, 1985): these are more or less explicit customs established in some industries to allow for price coordination. Examples are the best-price guarantee given to a customer, either with respect to other sellers ("meet-or-release" clause) or with respect to other customers ("most-favored-customer" clause) and the practice of public advance notification of price increases.³ However, we do not introduce pricing schemes here as corresponding to well-specified price-formation mechanisms used in particular industries. They are seen as an explicit but formal representation of the coordination of pricing

decisions that is reached in an industry for a homogeneous product (maybe after a long process) and which is implicit in the use of the inverse demand function in Cournot's traditional approach.

Furthermore, by introducing pricing schemes, we allow for a more natural definition of Cournotian oligopolistic competition with several sectors, each containing several producers of the same homogeneous good, the market price in any one sector being fixed through its own respective pricing scheme. We thus get, in each sector, a well-defined juxtaposition of monopoly problems, one for each firm in the sector, contingent on the total quantity produced in the same sector and on the prices set in the other sectors. The benefit is to avoid assuming that the producers are able to carry over in their computation the inversion of a complete demand system, taking all cross-sectoral effects into account. In a general equilibrium model, this would lead to an alternative to the Cournot-Walras approach (as developed by Jean J. Gabszewicz and Jean-Philippe Vial [1972]) and to the market game approach (see e.g., Lloyd S. Shapley and Martin Shubik, 1977; Pradeep Dubey, 1981; Leo K. Simon, 1984).

The paper is organized as follows. In Section I, a formal concept of equilibrium with pricing schemes is compared to the Cournot equilibrium and then, in Section II, it is illustrated for a particular scheme, the min-pricing scheme. In Section III, it is extended to the multisectoral case generalizing both the Cournot and the monopolistic competition concepts.

I. Pricing Schemes in the Cournot Model

In this section, we consider the market for a single homogeneous good with an extended real-valued demand function D , defined on \mathbb{R}_+ , and a set $N = \{1, \dots, i, \dots, n\}$ of firms. Each firm $i \in N$ can produce any quantity $y_i \geq 0$, at a nonnegative cost $C_i(y_i)$, and choose any price signal $\psi_i \geq 0$. Each C_i is a continuous increasing function on \mathbb{R}_+ . As discussed in the introduction, the market price is supposed to be determined by a pricing scheme P , a continuous nondecreas-

³The main result of the facilitating-practice literature is to show how such clauses can implement prices above the competitive price. For example Ehud Kalai and Mark A. Satterthwaite (1986) and Christopher Doyle (1988) get the implementation of the collusive price. However, by introducing discount possibilities below list prices in a second stage, Charles A. Holt and David T. Scheffman (1987) get the Cournot price as the maximal implementable price. For an experimental approach, see David M. Grether and Charles R. Plott (1984).

ing function from \mathbb{R}_+^n to \mathbb{R}_+ , associating with each vector of price signals $\psi = (\psi_1, \dots, \psi_i, \dots, \psi_n)$ a single price $P(\psi)$. For a given pricing scheme P , we thus obtain a game involving the n firms, the strategies of firm i being the set of nonnegative quantity-price pairs (y_i, ψ_i) and, for any vector (\mathbf{y}, ψ) of such strategies, the payoff of firm i being given by the profit function

$$\Pi_i(\mathbf{y}, \psi) \equiv y_i P(\psi) - C_i(y_i).$$

In addition, a feasibility constraint is imposed on (\mathbf{y}, ψ) in the strategy set:

$$Y \equiv \sum_{i=1}^n y_i \leq D(P(\psi)).$$

Then, letting $\mathbf{y}_{-i} \equiv (y_1, \dots, y_{i-1}, y_{i+1}, \dots, y_n) \in \mathbb{R}_+^{n-1}$ (and defining ψ_{-i} similarly) and also $Y_{-i} \equiv \sum_{j \neq i} y_j$, we define a P -equilibrium as a vector (\mathbf{y}^*, ψ^*) in \mathbb{R}_+^{2n} , such that $Y^* = D(P(\psi^*))$ and, for every $i \in N$, (y_i^*, ψ_i^*) is a solution to

$$\max_{(y_i, \psi_i)} y_i P(\psi_i, \psi_{-i}^*) - C_i(y_i)$$

such that $y_i \leq D(P(\psi_i, \psi_{-i}^*)) - Y_{-i}^*$, $y_i \geq 0$, $\psi_i \geq 0$. To find the Cournot equilibrium in this way, it is clear that pricing schemes have to be more precisely specified. Three classes will be discussed, varying according to the degree of control each firm has on the market price. They are schemes such that (1) all firms together exercise complete control, (2) each individual firm has local control, or (3) each individual firm has complete control on the market price. Property (1) is minimal and amounts to requiring that P has full range: $P(\mathbb{R}_+^n) = \mathbb{R}_+$. However, the main feature distinguishing Cournotian competition from perfect competition is the influence an individual firm may have on the market price. Hence, property (2) requires that the pricing scheme P be strictly increasing in each variable ψ_i . Abstract pricing schemes satisfying these first two properties are, for example, the "arithmetic mean" $\bar{P}(\psi) = (\sum_{i=1}^n \psi_i)/n$, and the "harmonic mean" $\hat{P}(\psi) = n / [\sum_{i=1}^n (1/\psi_i)]$ if $\psi \gg 0$ ($\hat{P}(\psi) = 0$, otherwise). By contrast, the "min-pricing scheme" $P^{\min}(\psi) = \min_j \{\psi_j\}$ and the "max-

pricing scheme" $P^{\max}(\psi) = \max_j \{\psi_j\}$, which have full range, are not strictly increasing in ψ_i . One may go further and consider as property (3) that, for every $i \in N$ and $\psi_{-i} \in \mathbb{R}_+^{n-1}$, $P(0, \psi_{-i}) = 0$ and, for $\psi_i \gg 0$, $P(\cdot, \psi_{-i})$ has full range. This property is not satisfied by the previous examples: the arithmetic mean and the max-pricing scheme give complete control to the individual firms only "upwards"; the harmonic mean and the min-pricing scheme give complete control only "downwards." A pricing scheme satisfying all three properties is the "geometric mean" $\bar{P}(\psi) = [\prod_{i=1}^n \psi_i]^{1/n}$. We shall denote by \mathcal{P}_1 , \mathcal{P}_2 , and \mathcal{P}_3 the sets of pricing schemes satisfying respectively the first, the first two, and all three properties. The interest in considering these classes of pricing schemes is that they imply a close relationship between P -equilibria and Cournot equilibria. This is exhibited in Proposition 1 below.

Recall that, whenever the inverse demand function D^{-1} is well defined [i.e., continuous, decreasing on \mathbb{R}_+ , and such that, for $0 < Y < D(0)$, $D^{-1}(Y) = p$ if and only if $D(p) = Y$] and nontrivial [i.e., $D^{-1}(Y) > 0$ for some $Y > 0$] a Cournot equilibrium is a quantity vector $\mathbf{y}^c \in \mathbb{R}_+^n$ such that, for every $i \in N$, y_i^c is a solution to

$$\max_{y_i \geq 0} y_i D^{-1}(Y_{-i}^c + y_i) - C_i(y_i)$$

$$\text{with } Y_{-i}^c = \sum_{j \neq i} y_j^c.$$

We may then show the following.

PROPOSITION 1: *Let the inverse demand function D^{-1} be well defined and nontrivial. We have:*

- (a) *For any pricing scheme $P \in \mathcal{P}_1$, if \mathbf{y}^c is a Cournot equilibrium, then (\mathbf{y}^c, ψ^c) is a P -equilibrium where ψ^c is chosen so that $P(\psi^c) = D^{-1}(Y^c)$.*
- (b) *For any pricing scheme $P \in \mathcal{P}_3$, if (\mathbf{y}^*, ψ^*) is a P -equilibrium, then \mathbf{y}^* is a Cournot equilibrium.*
- (c) *Assume that the profit $[y_i D^{-1}(Y_{-i} + y_i) - C_i(y_i)]$ is a strictly quasi-concave function of y_i for every $Y_{-i} \in \mathbb{R}_+$ and every $i \in N$. For any pricing scheme $P \in \mathcal{P}_2$, if*

(\mathbf{y}^*, Ψ^*) is a P -equilibrium, then \mathbf{y}^* is a Cournot equilibrium.

PROOF:

(a) Consider a Cournot equilibrium \mathbf{y}^c and take any $P \in \mathcal{P}_1$. Because P has full range, we can pick $\Psi^c \in \mathbb{R}_+^n$ such that $P(\Psi^c) = D^{-1}(Y^c)$. Suppose (\mathbf{y}^c, Ψ^c) is not a P -equilibrium; that is, $y_i^c P(\psi_i^0, \Psi_{-i}^c) - C_i(y_i^c) > y_i^c P(\Psi^c) - C_i(y_i^c)$ and $y_i^0 \leq D(P(\psi_i^0, \Psi_{-i}^c)) - Y_{-i}^c$, for some $i \in N$, $\psi_i^0 \geq 0$ and $y_i^0 \geq 0$. Since D^{-1} is well defined, the second inequality implies

$$D^{-1}(Y_{-i}^c + y_i^0) \geq P(\psi_i^0, \Psi_{-i}^c)$$

so that,

$$\begin{aligned} y_i^0 D^{-1}(Y_{-i}^c + y_i^0) - C_i(y_i^0) \\ > y_i^c D^{-1}(Y^c) - C_i(y_i^c) \end{aligned}$$

which is a contradiction to \mathbf{y}^c being a Cournot equilibrium.

(b) For $P \in \mathcal{P}_3$, suppose (\mathbf{y}^*, Ψ^*) is a P -equilibrium but \mathbf{y}^* is not a Cournot equilibrium; that is, for some $y_i^0 \geq 0$ and $i \in N$,

$$\begin{aligned} y_i^0 D^{-1}(Y_{-i}^* + y_i^0) - C_i(y_i^0) \\ > y_i^* D^{-1}(Y^*) - C_i(y_i^*) \end{aligned}$$

and

$$D^{-1}(Y^*) = P(\Psi^*) > 0.$$

Since i has complete control, there is $\psi_i^0 \geq 0$ such that $P(\psi_i^0, \Psi_{-i}^*) = D^{-1}(Y_{-i}^* + y_i^0)$ and

$$\begin{aligned} y_i^0 P(\psi_i^0, \Psi_{-i}^*) - C_i(y_i^0) \\ > y_i^* P(\Psi^*) - C_i(y_i^*) \end{aligned}$$

which contradicts that (\mathbf{y}^*, Ψ^*) is a P -equilibrium.

(c) If $P \in \mathcal{P}_2$, the problem with the previous argument is that one cannot be sure to find $\psi_i^0 \geq 0$ such that $P(\psi_i^0, \Psi_{-i}^*) = D^{-1}(Y_{-i}^* + y_i^0)$. However, by strict quasi-concavity, one can find some y_i^0 satisfying the above strict inequality arbitrarily close

to y_i^* and, hence, some ψ_i^0 such that $P(\psi_i^0, \Psi_{-i}^*) = D^{-1}(Y_{-i}^* + y_i^0)$, since $P(\cdot, \Psi_{-i}^*)$ is strictly increasing. The result follows.

Now, given a pricing scheme P and a P -equilibrium (\mathbf{y}^*, Ψ^*) , we denote by B_i^* the set of prices

$$\arg \sup_{p \geq 0} \{p[D(p) - Y_{-i}^*] - C_i(D(p) - Y_{-i}^*)\}$$

subject to

$$D(p) - Y_{-i}^* \geq 0.$$

This set may include $p = \infty$. We see that B_i^* is the set of prices among which firm i would choose if it were a monopolist facing the residual demand $[D(p) - Y_{-i}^*]$. We shall call firm i a " P -leader" at (\mathbf{y}^*, Ψ^*) whenever $P(\Psi^*) \in B_i^*$. A firm i that is not a P -leader at (\mathbf{y}^*, Ψ^*) will be called a " P -follower." Then, y_i^* is a solution to

$$\max_{y_i \geq 0} P(\Psi^*) y_i - C_i(y_i)$$

subject to

$$y_i \leq D(P(\Psi^*)) - Y_{-i}^*.$$

We see that a P -follower⁴ can only be a price-taker with respect to the price $P(\Psi^*)$. The next proposition shows how the Cournot equilibrium can be interpreted. At a Cournot equilibrium, each firm behaves as a monopolist facing the residual demand.

PROPOSITION 2: *If the inverse demand function D^{-1} is well defined and nontrivial, then, for any full-range pricing scheme ($P \in \mathcal{P}_1$) and any P -equilibrium (\mathbf{y}^*, Ψ^*) , \mathbf{y}^* is a Cournot equilibrium if and only if all firms are P -leaders at (\mathbf{y}^*, Ψ^*) .*

PROOF:

Suppose first that \mathbf{y}^* is not a Cournot equilibrium. Then, for some $i \in N$ and

⁴ If i is a P -leader, then y_i^* is also a solution to this program; otherwise (\mathbf{y}^*, Ψ^*) would not be a P -equilibrium. The difference is that the leader chooses an optimal price.

$$y_i^0 \geq 0,$$

$$\begin{aligned} & y_i^0 D^{-1}(Y_{-i}^* + y_i^0) - C_i(y_i^0) \\ & > y_i^* D^{-1}(Y^*) - C_i(y_i^*) \\ & \text{with } D^{-1}(Y^*) = P(\Psi^*). \end{aligned}$$

Then, taking $p^0 = D^{-1}(Y_{-i}^* + y_i^0)$, we see immediately that i cannot be a P -leader. Now, if y^* is a Cournot equilibrium, then (y^*, Ψ^*) is a P -equilibrium (in the first part of Proposition 1 we need only that P be of full range). Thus, if i is not a P -leader, for some $p^0 \geq 0$, we must have,

$$\begin{aligned} & p^0 [D(p^0) - Y_{-i}^*] - C_i(D(p^0) - Y_{-i}^*) \\ & > P(\Psi^*) [D(P(\Psi^*)) - Y_{-i}^*] \\ & \quad - C_i(D(P(\Psi^*)) - Y_{-i}^*) \end{aligned}$$

or, letting $y_i^0 = D(p^0) - Y_{-i}^* \geq 0$ [and $p^0 = D^{-1}(Y_{-i}^* + y_i^0)$], we obtain the same strict inequality as above [since $y_i^* = D(P(\Psi^*)) - Y_{-i}^*$], contradicting that y^* is a Cournot equilibrium.

This leads to a typology of P -equilibria. Besides the P -equilibrium in which all firms are P -leaders and which is of a Cournot type, we have P -equilibria in which all firms are P -followers and which include the Bertrand-type equilibrium, and we also have those in which some firms are P -leaders and some are P -followers. This is clarified in the following example, in which all types of P -equilibria can be exhibited for a particular pricing scheme, the min-pricing scheme P^{\min} .

II. The Special Case of the Min-Pricing Scheme

Consider two firms, with a linear demand function,

$$D(p) = \max\{0, a - bp\} \quad a > 0, b > 0$$

and for each firm i , the same twice continuously differentiable cost function C_i with $C' > 0$, $C'' > 0$, and $C(0) = C'(0) = 0$. Let

FIGURE 1. SYMMETRIC P^{\min} -EQUILIBRIA

$\eta(p) \equiv -p[D'(p)/D(p)]$ denote the price elasticity. Here $\eta(p) = bp/(a - bp)$. The first-order conditions for a Cournot equilibrium y^c are well known to be

$$p^c \left[1 - \frac{y_i^c}{y_i^c + y_j^c} \frac{1}{\eta(p^c)} \right] = C'(y_i^c)$$

with $y_i^c + y_j^c = D(p^c)$, $i \neq j$. Here, this clearly implies $y_i^c = y_j^c = y_c$ and is simply given by the solution of

$$\frac{1}{b}(a - 3y_c) = C'(y_c).$$

This can be interpreted as a symmetric P^{\min} -equilibrium in which both firms are P -leaders (by Proposition 2), by letting $\psi_1^* = \psi_2^* = p^c$ and $y_1^* = y_2^* = y_c$. This symmetric P^{\min} -equilibrium appears as point C in Figure 1.

There are other symmetric P^{\min} -equilibria for which, on the contrary, all firms are P -followers: each would prefer to increase the price but cannot individually do so. Therefore, each produces as much as possible considering the residual demand, as long as the market price is higher than the marginal cost. It is as if firms were facing "kinked" demand curves, with the

equilibrium corresponding to the “kink,” the point at which there is a discontinuity in the marginal revenue. Two such equilibria are illustrated by points A and B in Figure 1. Point A corresponds to the symmetric P^{\min} -equilibrium with $\psi_1^* = \psi_2^* = \bar{p}$ and $y_1^* = y_2^* = \bar{y}$ and satisfies the conditions

$$\bar{p} \left[1 - \frac{1}{2} \left(\frac{1}{\eta(\bar{p})} \right) \right] < C'(\bar{y}) < \bar{p}.$$

Point B corresponds to the symmetric P^{\min} -equilibrium with $\psi_1^* = \psi_2^* = p^b$ and $y_1^* = y_2^* = y_b$ and satisfies the conditions

$$p^b \left[1 - \frac{1}{2} \left(\frac{1}{\eta(p^b)} \right) \right] < C'(y_b) = p^b.$$

It is in fact a Bertrand equilibrium. There is a continuum of symmetric P^{\min} -equilibria of the type given by point A between points B and C, corresponding to prices between p^b and p^c . No symmetric P^{\min} -equilibrium corresponds to prices below p^b , since then the equilibrium condition $D(\min\{\psi_1^*, \psi_2^*\}) = Y^*$ cannot be satisfied. Also there are no P^{\min} -equilibria corresponding to prices above the Cournot price p^c .⁵

There are also nonsymmetric P^{\min} -equilibria. These would consist of vectors $(\mathbf{y}^*, \boldsymbol{\psi}^*)$ such that, for $p^* = \min\{\psi_1^*, \psi_2^*\}$,

$$p^* \left[1 - \frac{y_i^*}{Y^*} \left(\frac{1}{\eta(p^*)} \right) \right] = C'(y_i^*) \quad \text{for some } i \in \{1, 2\}$$

$$p^* \geq C'(y_j^*) > p^* \left[1 - \frac{y_j^*}{Y^*} \left(\frac{1}{\eta(p^*)} \right) \right]$$

for $j \neq i$.

This implies that $y_j^* > y_i^*$ and is illustrated in Figure 2. This is a “price leadership” type of equilibrium: i is the price-maker, j is the price-taker (as such, firm j could even

FIGURE 2. NONSYMMETRIC P^{\min} -EQUILIBRIA

be at a point where $\min\{\psi_1^*, \psi_2^*\} = C'(y_j^*)$,
but no further).

III. A Simple Multisectoral Extension

The advantage of the approach of oligopoly via pricing schemes is to allow straightforward extension of a Cournot-type equilibrium concept to the multisector case. Indeed, the usual definition of the Cournot equilibrium requires the definition of the inverse demand function to reduce the strategy space of each firm to the choice of a quantity. However, in the multisector case, the demand in each sector depends on the price in the other sectors, and so one has to invert a complete demand system as in the Cournot-Walras approach (see Gabszewicz and Vial, 1972). This implies that even stronger conditions have to be imposed before defining the equilibrium concept. Moreover, the inverse demand system thus obtained might not facilitate the interpretation of the additional restrictions needed later to prove existence. Using pricing schemes, we can define directly the equilibrium concept and postpone the introduction of specific assumptions to the time when the existence problem would have to be examined.

Suppose we have m goods, each one homogeneous, and that the market for each

⁵In their two-stage procedure Holt and Scheffman (1987) reach the same conclusions for the symmetric case (see their proposition 2).

good k is characterized by an extended real-valued demand function D_k , defined for any vector of nonnegative prices $\mathbf{p} \equiv (p^1, \dots, p^k, \dots, p^m) \in \mathbb{R}_+^m$. Also, in each sector k , we have a set N^k of n^k firms. Each firm $i \in N^k$ can produce a quantity $y_i \in \mathbb{R}_+$ of good k and has a continuous increasing cost function $C_i(y_i)$. In the market for good k , the price is determined by a pricing scheme P^k , a continuous nondecreasing function of the price signals of all firms in sector k ; say $\Psi^k = (\psi_i^k)_{i \in N^k} \in \mathbb{R}_+^{n^k}$. Letting $Y^k \equiv \sum_{i \in N^k} y_i$, $Y_{-i}^k \equiv \sum_{j \in N^k \setminus \{i\}} y_j$, for $k = 1, \dots, m$, and $\mathbf{P} = (P^1, \dots, P^k, \dots, P^m)$, we define a P -equilibrium as a vector (\mathbf{y}^*, Ψ^*) in $\mathbb{R}_+^n \times \mathbb{R}_+^n$ such that, for $k = 1, \dots, m$, $Y^k = D^k(P(\Psi^*))$ with $P(\Psi^*) = (P^1(\Psi^*), \dots, P^m(\Psi^*))$, and for every $i \in N^k$, (y_i^*, ψ_i^*) is a solution to

$$\max_{(y_i, \psi_i)} y_i P^k(\psi_i, \Psi_{-i}^*) - C_i(y_i)$$

subject to

$$y_i \leq D^k(P(\psi_i, \Psi_{-i}^*)) - Y_{-i}^k, y_i \geq 0, \psi_i \geq 0.$$

From the preceding section, we know that to get Cournot-type equilibria we have to require at least that $P_k \in \mathcal{D}_2$ for every k . In fact, the equilibrium we obtain then can be described without referring to any pricing scheme. Indeed, it amounts to having a pair of prices and quantities $(\mathbf{p}^*, \mathbf{y}^*)$ in $\mathbb{R}_+^m \times \mathbb{R}_+^n$ such that each firm i in each sector k is (at least locally) a P^k -leader: it behaves as a price-setting monopolist facing the demand function $[D^k(\cdot, \mathbf{p}^{-k*}) - Y_{-i}^{k*}]$ which is contingent on the other equilibrium prices \mathbf{p}^{-k*} and the equilibrium total quantity of good k , Y_{-i}^{k*} , produced by the other firms of sector k . This equilibrium concept can be defined independently from pricing schemes and may be called a *Cournotian monopolistic competition equilibrium*. Thus, for this equilibrium concept, pricing schemes appear simply as formal devices allowing one to model the coordination between producers who are all conscious of their own influence on their market price, without computing the inverse of the complete demand system.

IV. Conclusion

In this paper, we have proposed a reinterpretation of Cournot equilibrium based on a general and formal coordination device, the pricing scheme, satisfying some global and individual responsiveness properties. The exact determination of this device is not required. For the multisectoral case, we get an equilibrium concept that generalizes both the Cournot equilibrium and the monopolistic competition equilibrium (i.e., if there is one sector, it generalizes Cournot; if there is only one firm per sector, it generalizes monopolistic competition). The more general equilibrium concept to which it leads, the Cournotian monopolistic competition equilibrium, can be described as the solution to the juxtaposition of many monopoly problems, each monopolist facing a demand function contingent on the equilibrium quantities produced in its sector and on the equilibrium prices set in the other sectors. We leave for future work the existence problem for such a concept in a general-equilibrium framework.

Redistribution and Capital Formation

By PETER RANGAZAS*

The conventional view regarding the macroeconomic effects of redistribution from the rich to the poor is that it will lower aggregate savings and physical capital accumulation. Savings will fall because the marginal propensity to save is thought to be higher for the rich than for the poor. Working from a life-cycle framework, Laurence Kotlikoff (1984 p. 1598) pointed out that there is little empirical support for this view and, in fact, there are several *a priori* reasons to believe it may *not* be true. Alan Blinder (1975) extended the life-cycle model to include a taste-for-bequest motive and examined the same issue. He showed that, if households systematically differ solely according to their permanent incomes, then aggregate savings will fall with lump-sum redistribution only if bequests are a luxury good; otherwise, savings may remain the same or rise.

One argument in the conventional view's favor is based on models of altruistically motivated intergenerational transfers.¹ In these models, rich families, who can afford to make efficient levels of human capital investments in their children, typically have enough wealth to make sizable bequests of financial assets. Poorer families, on the other hand, make their planned bequests exclusively in the form of human capital expenditures. No planned financial bequests are

made by these families because the return on the inefficiently low levels of human capital exceeds that on financial assets. In this case, a marginal redistribution of wealth would apparently lower aggregate savings, due to a reduction in financial bequests made by the rich with no compensating increase by the poor. Human capital production, however, would apparently increase. Transfers from rich to poor families would not alter the efficient investment in rich children, since for these families only financial bequests would be affected at the margin, but such transfers would raise human capital investment in poorer families (Gary Becker, 1981 pp. 121–2). While this argument in support of the conventional view has recently been emphasized by several authors (Blinder, 1976; Becker, 1981; Becker and Nigel Tomses, 1986), Paul Menchik and Martin David (1983) have traced it all the way back to Marshall's *Principles of Economics*.

In this paper, I show that the argument in favor of the conventional wisdom is only valid for a temporary (one generation) policy of redistribution, with fixed factor prices. Altering either the temporary nature of the policy or the fixed-price assumption allows the conclusions to be reversed under fairly general conditions. Relaxing the fixed-price assumption is a natural extension of the existing analysis which needs little defense. The distinction between permanent and temporary policies also clearly becomes important if families remain unconstrained (or constrained) for more than one generation.²

*Department of Economics, Indiana University-Purdue University at Indianapolis, Indianapolis, IN 46202. I am grateful to William Lord for useful discussions on the topic and to Sharon Zehr Rangazas for her assistance and comments. The paper also greatly benefited from the many thoughtful suggestions offered by the referees.

¹The extent to which any model focusing on bequests is empirically relevant for capital formation depends on the role of bequests motives relative to life-cycle factors in determining aggregate savings (see the recent debate on this topic between Franco Modigliani [1988] and Kotlikoff [1988]). For criticisms of the importance of altruistic bequests in particular, see Bernheim (1989 pp. 66–7).

²This will depend, in part, on how fast families regress toward the mean of wealth. Jere Behrman and Paul Taubman (1985) and Becker and Tomses (1986) find strong regression toward the mean in earnings. On the other hand, Menchik (1979) finds a great deal of wealth immobility for rich households, and Gary Solon et al. (1987) produce evidence suggesting substantial immobility for low-income families. Christopher Ruhm (1988) presents a theoretical model in which a family

For example, if an unconstrained household has a unit of wealth taxed away but also knows the policy applies to its children, then bequests savings will not necessarily fall. The outcome depends on the size of opposing marginal propensities to bequeath out of parents' and children's lifetime wealth.

I. The Microeconomic Model

Consider a household, headed by parents who live for one period.³ In each period, the parents choose lifetime consumption (c_t), expenditures per child (x_t), and a financial bequest (B_t), which is divided evenly among the children.⁴ The financial bequest is the amount by which parents plan to augment the wealth of their children, net of taxes and interest payments. The portion of lifetime wealth that must be set aside to accomplish this transfer is defined to be $p_t B_t$, where $p_t = (1 + r_{t+1})^{-1}$ may be interpreted as the price of making a transfer of net wealth to children.

There are $n_{t+1} = (1 + g)$ identical children per household, where g is the population growth rate. The household receives satisfaction from its own consumption and the total lifetime wealth of its children. The problem confronting the household is then

to maximize the following utility function:

$$(1) \quad U = u(c_t, W_{t+1} n_{t+1})$$

subject to its lifetime wealth constraint

$$(2) \quad c_t + n_{t+1} x_t + p_t B_t = W_t$$

where $W_t = I_t + R_t - T_t + w_t h_t$, in which I_t is inherited wealth, R_t is a lump-sum transfer made by the government, T_t is a lump-sum tax, and $w_t h_t$ is lifetime earnings. The variable w_t is the wage rate, and h_t is the stock of human capital. This stock is a function of last period's parental expenditures on education, x_{t-1} :

$$(3) \quad h_t = h(x_{t-1}).$$

The first-order conditions are

$$(4a) \quad u_1 = \lambda_t$$

$$(4b) \quad u_2 w_{t+1} h' = \lambda_t$$

$$(4c) \quad u_2 \leq p_t \lambda_t$$

$$B_t [u_2 - p_t \lambda_t] = 0 \quad B_t \geq 0$$

and (2).

A. Unconstrained Household

For the unconstrained household (UH), (4c) holds with equality, and a positive financial bequest is left. Using (4c), (4b) can be rewritten as

$$(4b') \quad p_t w_{t+1} h' = 1.$$

This equation is used to solve for the efficient level of human capital expenditures in terms of wage rate and the market discount factor, independent of other household decisions, to obtain

$$(5a) \quad X_t = X(p_t, w_{t+1})$$

where capital letters will be used to distinguish unconstrained choices from constrained choices. The efficient human capi-

can remain constrained permanently. My argument requires families to remain either constrained or unconstrained for at least two successive generations.

³As in previous models of this type, I abstract away from life-cycle issues and sex differences. However, I shall refer to "parents" in order to simplify the exposition. One may take the last year of economic dependency to be 21 and assume that each parent has children at, say, age 30, nine years into the period of economic independence. Then, each period corresponds to roughly 30 years.

⁴As long as attention is restricted to the macroeconomic effects of a lump-sum redistribution from unconstrained to constrained families, allowing for two children of different abilities, both of whom either receive some financial bequests or none at all, would complicate but would not essentially generalize the identical-children model. Analyzing the distribution of wealth across individuals may be more interesting in this setting, but that is a topic for another paper.

tal expenditures are then subtracted from the current generation's wealth, and the efficient human capital bequest is substituted into the next generation's wealth. The utility-maximizing consumption and financial-bequest decisions are determined next by using (4a) and the current-period budget constraint. The functions describing these choices are

$$(5b) \quad C_t = C(p_t, \overset{(+)}{\widetilde{W}}_{t+1}, \overset{(+)}{\overline{W}}_t)$$

$$(5c) \quad B_t = B(p_t, \overset{(-)}{\widetilde{W}}_{t+1}, \overset{(+)}{\overline{W}}_t)$$

where

$$\widetilde{W}_{t+1} = (w_{t+1}H[X(p_t, w_{t+1})] - T_{t+1})n_{t+1}$$

is total wealth of the children inclusive of their human capital bequest and exclusive of their financial inheritance and where $\overline{W}_t = B_{t-1}/(1+g) + w_t H_t - n_{t+1}X_t - T_{t+1}$ is the total wealth of the parents exclusive of the efficient human capital expenditures. The impact of a change in p_t , a function of the interest rate, will be discussed in the general-equilibrium portion of Section II.

The unique aspect of an altruistic model of intergenerational transfers is that consumption and financial bequests will be affected by \widetilde{W}_{t+1} , the wealth of the children independent of financial inheritances. The greater is the child's wealth from other sources, the smaller is the financial bequest and the greater is parental consumption. This can be explained by noting that $\partial B_t / \partial \widetilde{W}_{t+1} = -1 + (\partial B_t / \partial \overline{W}_t)p_t$, which decomposes the total effect into a substitution and a wealth effect.⁵ An exogenous increase in the child's wealth causes B_t to fall one-for-one, a direct substitution effect. Smaller expenditures on net bequests raise the parent's wealth by p_t . Since $(\partial B_t / \partial \overline{W}_t)p_t < 1$, this

will mitigate, but not offset, the direct substitution effect.⁶

Another way of interpreting the wealth effect is from the perspective of a consolidated family-budget constraint. When the next generation's wealth exogenously increases by one unit, the present value of family wealth increases by p_t . The extent to which the increase in family wealth is passed on to the next generation is determined by $\partial B_t / \partial \overline{W}_t$.

B. Constrained Household

For the constrained household (CH), $u_2 < p_t \lambda_t$ in (4c), and with the rate of return on human capital $(w_{t+1}h' - 1)$ exceeding that on financial bequests (r_{t+1}) , it is optimal to set $B_t = 0$. There is no separation of human capital decisions and consumption in this case. Equations (4a), (4b), and (2) must be simultaneously solved for c_t , x_t , and λ_t . Solutions of this problem produce demand functions of the form

$$(6a) \quad x_t = x(w_{t+1}, \overset{(-)}{R}_{t+1}, \overset{(+)}{\overline{W}}_t)$$

$$(6b) \quad c_t = c(w_{t+1}, \overset{(+)}{R}_{t+1}, \overset{(+)}{\overline{W}}_t).$$

Due to the simultaneous nature of the solution, wealth variables now influence human capital expenditures, and the wage rate now influences consumption. A change in \overline{W}_t induces a simple wealth effect on x_t and c_t , both of which are assumed to be normal goods. Any predictable exogenous increase in the wealth of the children (R_{t+1}) will lower x_t and raise c_t . Intuitively, constrained parents share some of the children's good fortune by diverting resources toward themselves. The effect of a higher anticipated wage rate for the next generation is ambiguous and will be discussed in detail when general-equilibrium considerations are introduced in the next section.

⁵The compensated demands are found by solving the dual to the maximization problem given by (1) and (2). Equating ordinary demands to compensated demands, substituting the expenditure function to form an identity, and then differentiating gives the Hicks decomposition.

⁶Tomes (1981) and Kotlikoff (1989 Ch. 16) provide empirical support for the sign of this effect.

II. Redistribution

In this section, I discuss the effects of redistribution on capital formation. Previous studies have concentrated on the partial-equilibrium effects of a temporary redistribution of wealth. At best, this represents a starting point for a complete general-equilibrium analysis of a permanent redistribution policy. I first show that the partial-equilibrium effects of permanent and temporary policies are quite different. The general-equilibrium effects of both policies are then analyzed to assess when the partial-equilibrium impact effects may be misleading.

A. Impact Effects

The bequest savings of the unconstrained household is $S_t = p_t B_t$. Substituting (5c) into the savings expression yields a savings function in terms of the other variables in the model. Consider the direct effect of a permanent increase in lump-sum taxation on S_t . Setting $T_t = T_{t+1} = T$ and differentiating the savings function gives

$$(9) \quad \partial S_t / \partial T = -p_t \left[(\partial B_t / \partial \widetilde{W}_{t+1})(1+g) + \partial B_t / \partial \overline{W}_t \right].$$

The expression is opposite in sign and equal in absolute value to a permanent increase in the wealth of the UH. Greater wealth for the current generation will raise bequests ($\partial B_t / \partial \widetilde{W}_t$), but greater wealth for each member of the next generation will lower bequests ($\partial B_t / \partial \widetilde{W}_{t+1}[1+g]$). Since from the microeconomic analysis of the UH one knows that $\partial B_t / \partial \widetilde{W}_{t+1} = -1 + p_t \partial B_t / \partial \overline{W}_t$, an estimate of the marginal propensity to bequeath is sufficient to resolve the issue. Menchik and David (1983 p. 683) estimate $p_t \partial B_t / \partial \overline{W}_t$ to be 0.25.⁷ This implies

⁷One can also construct estimates from Tomes (1981). His table 4 is the most relevant, since there he isolates the pure effect of income changes across generations, holding constant compensating variations in transfers due to differences in income across children. The estimates of $p_t \partial B_t / \partial \overline{W}_t$ range from 0.12 to 0.16,

$\partial B_t / \partial \widetilde{W}_{t+1}(1+g) < -0.75$, suggesting that bequests fall with a rise in the permanent wealth of the family.⁸ Intuitively, given what is known about the marginal propensity to bequeath, the substitution effect of a permanent rise in family wealth is dominant, which causes parents to reduce bequests whenever they realize that the next generation is also better off.⁹

An example may help to uncover the structural factors leading to such a result. If the utility function is assumed to take the commonly employed CES form,

$$[1/(1-\sigma)]c_t^{1-\sigma} + [b/(1-\gamma)][W_{t+1}(1+g)]^{1-\gamma}$$

then (9) can be rewritten as

$$(9') \quad \frac{\partial S_t}{\partial T} = \frac{-p_t}{D} \left\{ 1 - \left(\frac{\gamma}{\sigma} \right) \left(\frac{c_t}{(\widetilde{W}_{t+1} + B_t)/(1+g)} \right) \right\}$$

where $D = p_t + (\gamma/\sigma)[c_t/(\widetilde{W}_{t+1} + B_t)] > 0$. If preferences are homothetic, $\gamma = \sigma$, then savings will increase with a permanent tax increase only if parents' consumption exceeds wealth per child, $c_t > (\widetilde{W}_{t+1} + B_t)/(1+g)$. This is certainly a possibility if there is some regression toward the mean in wealth. Consider, however, the stationary case in which wealth is equal across gen-

assuming a 40-year work life and an after-tax annual interest rate of 3 percent, as in Menchik and David (1983).

⁸Table 4 in Tomes (1981) also gives direct evidence in support of this result.

⁹This sign can be resolved more generally by writing out $\partial S_t / \partial T$, with all subscripts dropped for convenience, as

$$- \{ -[1 - (\partial B / \partial \overline{W})(1+g)/(1+r)] + \partial B / \partial \overline{W} \} \\ = (1+g)/(1+r)[1 - (\partial B / \partial \overline{W})\delta]$$

where $\delta = [(1+g) + (1+r)]/[(1+g)(1+r)] \leq 1$ if $1 \leq rg$. Taking each period to be roughly 30 years, as explained in footnote 3, with an annual population growth of 1.5 percent (each household then having approximately 1.5 children) and an annual real interest rate of 4 percent (see Edward C. Prescott, 1986), $rg = 1.26$. Thus, as long as $\partial B / \partial \overline{W} < 1$, the direct effect of a permanent lump-sum tax on the UH is to raise steady-state bequests and savings.

erations, $W_t = (\widetilde{W}_{t+1} + B_t)/(1+g) = W_{t+1}$. In this case, $c_t < (\widetilde{W}_{t+1} + B_t)/(1+g)$, because expenditures on human and financial bequests are positive. Thus, when wealth is equal across generations, preferences must be nonhomothetic ($\gamma > \sigma$) for bequests to increase with a permanent increase in taxes.

It is important to note that, unlike in Blinder's (1975) taste-bequest model, $\gamma > \sigma$ does not imply that the parental-wealth elasticity of bequests is less than 1. In an altruistic model, homothetic preferences imply a parental-wealth elasticity that is strictly greater than 1.¹⁰ Intuitively, bequests must move much more than proportionately with parents' wealth to allow the future generation's wealth to move proportionately. Therefore, the fact that bequests may fall with a permanent increase in family wealth is in no way inconsistent with the apparent empirical fact that bequests are luxury goods with respect to parents' wealth.

Now consider a permanent transfer to the constrained family. With $R_t = R_{t+1} = T$, the policy has the following impact effect on current-period human capital expenditures:

$$(10) \quad \partial x_t / \partial T = \partial x_t / \partial R_t + \partial x_t / \partial R_{t+1}.$$

As with the analysis of financial bequests, a permanent policy change produces opposing effects. However, unlike with financial bequests, there is no simple relationship between $\partial x_t / \partial R_{t+1}$ and $\partial x_t / \partial R_t$, forcing one to find estimates for *both* expressions.

Such estimates are understandably scarce, but some recent studies by Barry Chiswick and Donald Cox (1987) and Cox (1987a, b, c) are suggestive. These studies deal with the determinants of inter vivos transfers in general, rather than transfers for human capital per se. They also do not include transfers made before the recipient is 18 years of age. Nevertheless, there are some

relevant features of this work. Based on a representative cross-sectional survey of households, Cox (1987c) finds that those receiving transfers have lower current and permanent income than those not receiving transfers. Thus, the results evidently pertain to wealth-constrained families. Parents from constrained families appear to make modest transfers throughout their children's young life, rather than a larger efficient transfer early on and a financial bequest at death.

The most robust result of interest is that a permanent increase in the income of both the potential transfer recipient and his parents will increase the *likelihood* of a positive transfer.¹¹ Estimating the marginal impacts of income changes on the *level* of transfers, for those receiving transfers, is more difficult and here the empirical results are sensitive to the sample and empirical method chosen.¹² However, there is certainly no evidence to suggest that a permanent rise in family income will reduce parental transfers. If any conclusion can be drawn, it is that a permanent rise in income for the *aggregate* of wealth-constrained households will increase *aggregate* transfers by increasing the number of parents making transfers to children over 18 years old.

B. General-Equilibrium Considerations

Assuming that output is determined by a standard neoclassical production function,

¹¹ Compare the coefficients on recipient's income and the proxy for donor's income in tables 2 and 4 of Cox (1987a), column 1 in table 2 of Chiswick and Cox (1987), column a in table 5 of Cox (1987b), and tables 3, 4, and 7 of Cox (1987c). In the subsample including recipients as the secondary family unit, the studies above produce a positive, rather than negative, sign for recipient's income. The net effect is still, of course, positive.

¹² Both the sign and the statistical significance of recipient and donor income vary substantially. This may reflect the complexity of determining the factors influencing the marginal transfers from parents to children in wealth-constrained families. After the parents' altruism has been exhausted, the inefficient levels of human capital investment are likely to motivate implicit loan agreements between parents and children. The pure altruistic model does not address these types of exchanges.

¹⁰ See the discussion by Becker (1974). More precisely, one can readily couch the present model in the form of the theory from section 2 of his paper, to obtain the appropriate bequest formula from his equation 2.8.

markets are competitive, and, for convenience, the number of unconstrained and constrained households is the same implies

$$(11) \quad r_{t+1} = f'(K_{t+1}/[1+g][h_{t+1}+H_{t+1}])$$

where K_{t+1} is the capital stock per unconstrained household and f is the production function per unit of effective labor supply. This period's savings per unconstrained household provide the funds for next period's capital stock. With the past period's savings and human capital decisions taken as given at time t , equations (5) and (6) and the factor price frontier [$w_{t+1} = \varphi(r_{t+1})$, $\varphi' = -k_{t+1} = -K_{t+1}/(1+g)(h_{t+1}+H_{t+1})$] can be substituted into both (11) and the savings expression to produce

$$(12) \quad r_{t+1} = \rho(K_{t+1}, T_t, T_{t+1})$$

$$(13) \quad S_{t+1} = S(r_{t+1}, T_t, T_{t+1}).$$

In a representative-household model of bequest-savings, (12) can be sketched as a downward-sloping demand for capital, and (13) can be sketched as an upward-sloping supply of capital, holding transfers constant. However, with heterogeneous households, neither slope is restricted by theory alone. Before discussing why the slopes may become irregular and what consequences this may have for redistributive policy, it is interesting to point out that the conventional view does not necessarily follow in general equilibrium, even when the demand and supply curves have their regular slopes and the policy is temporary. An increase in T_t , holding T_{t+1} constant, shifts the supply curve leftward, as parental wealth of the UH falls, and shifts the demand curve rightward, as the increase in wealth and human capital expenditures of the CH at time t lowers the capital:labor ratio at time $t+1$, everything else held constant. This is depicted in Figure 1. The *equilibrium* level of savings may rise, fall, or remain the same depending on the relative size of the shifts. The only unambiguous effect is that real interest rates are higher and real wage rates are lower, which means that the human capital investment of the UH will be

FIGURE 1. AN INCREASE IN T_t , HOLDING T_{t+1} CONSTANT, SHIFTS THE SUPPLY CURVE LEFTWARD AND SHIFTS THE DEMAND CURVE RIGHTWARD

“crowded out” by the excess demand for funds generated by the policy. Nothing can be said about the physical capital stock or the aggregate human capital stock.¹³

For a permanent policy change, even the impact effects on the demand and supply curves are ambiguous. As discussed in the previous section, the available empirical evidence suggests that a permanent increase in T will shift the supply curve and, with less certainty, the demand curve rightward. If the demand curve is downward-sloping and the supply curve upward-sloping, the level of savings will unambiguously rise. The impact on factor prices is ambiguous, and as a result it is not clear whether aggregate human capital rises or falls. However, as previously mentioned, theory does not restrict the slopes of either curve in a model with heterogeneous households.

Starting on the supply side, the substitution effect of an increase in r_{t+1} makes

¹³The general equilibrium analysis of this section is short-run in nature, since we do not examine the transition to a new steady state. Such an analysis requires the strong assumption that families stay unconstrained or constrained permanently. A steady-state analysis is carried out in a longer working paper and is available upon request.

financial bequests cheaper relative to consumption and relative to human capital investment, leading to more savings. However, an increase in r_{t+1} also induces wealth effects which are less transparent. A higher r_{t+1} raises the next generation's wealth, for a given level of financial bequests. In general equilibrium, a higher r_{t+1} means a lower w_{t+1} , causing the next generation's labor income to fall. In a representative-household model, these two wealth effects just cancel, leaving bequests unaffected. With two households, this is not the case. A higher r_{t+1} transfers wealth from the CH of the next generation, via a lower w_{t+1} , to the UH of the next generation. Since the children of the UH are made better off, parent's bequests will fall. This conflicts with the substitution effect, making the overall effect ambiguous.

On the demand side, the ambiguity arises because a change in the wage rate has an ambiguous effect on effective labor supply. A rise in w_{t+1} clearly increases the human capital investment of the UH, but not of the CH. The effect of a higher anticipated wage rate on the investment of the CH can be decomposed as

$$(10) \quad \partial x_t / \partial w_{t+1} \\ = \partial \bar{x}_t / \partial w_{t+1} + (\partial x_t / \partial R_{t+1}) h.$$

The first term is the compensated-relative-price effect of a higher return on human capital investment, and its sign is positive. The second term reflects the fact that an increase in future wages works like an exogenous increase in the child's wealth, which lowers expenditures, making the overall effect ambiguous.

Due to the possibility of irregularly sloped demand and supply curves, the general-equilibrium results may differ from the direct partial-equilibrium impacts, even after assuming that the capital market is Hicksian stable (see Peter A. Diamond, 1965; Christophe Chamley and Brian D. Wright, 1987). There are two cases in which the impact effects may be misleading. First, consider the case with a downward-sloping supply curve as depicted in Figure 2. Rightward shifts of both curves may cause a rise

FIGURE 2. THE CASE WITH A DOWNWARD-SLOPING SUPPLY CURVE: RIGHTWARD SHIFTS OF BOTH CURVES MAY CAUSE BEQUEST-SAVINGS TO FALL IN EQUILIBRIUM

FIGURE 3. THE CASE WITH AN UPWARD-SLOPING DEMAND CURVE: RIGHTWARD SHIFTS OF BOTH CURVES MAY CAUSE BEQUEST-SAVINGS TO FALL IN EQUILIBRIUM

in interest rates which increases the wealth of the children from the UH to such an extent that bequest-savings fall in equilibrium. Second, if the demand curve is upward-sloping, rightward shifts of both curves may lower interest rates and, through a dominant substitution effect, lower savings in equilibrium as indicated in Figure 3.

III. Conclusion

Contrary to conventional belief, there is no compelling reason to believe that lump-sum redistribution will lower physical capital formation. Other authors have pointed this out for the case of life-cycle savings. The contribution of this paper is to make a similar point for the case of altruistically motivated bequests-savings. The available empirical evidence indicates that the direct effect of redistribution is to *raise* bequests for many households.

The paper also suggests that the equilibrium effects of redistribution on physical and human capital are difficult to ascertain in models with heterogeneous households, even when there is perfect knowledge concerning the impact effects. Work on a general-equilibrium simulation model with constrained and unconstrained households is currently underway. The best guess about the general-equilibrium effects of redistribution will most likely come from such a source.

The Welfare Economics of Price Supports in U.S. Agriculture: Comment

By GEOFF EDWARDS AND DAVID VANZETTI*

Erik Lichtenberg and David Zilberman (1986) (henceforth LZ) compare the effects of restrictions on pesticide use in United States agriculture with and without agricultural price supports. LZ's main conclusion is that price supports change the distribution of the costs of pesticide regulation. With their model specification, gains to producers from regulation in the absence of price supports became losses with a target price, while losses to consumers cum taxpayers became gains.

LZ say, and we agree, that estimating the costs of regulation "is one of economists' main contributions to the policy evaluation process" (p. 1135). A fundamental question in welfare economics is whose welfare is to be counted? LZ use a partial-equilibrium model that distinguishes welfare effects on U.S. farmers, U.S. taxpayers, and consumers. Implicitly welfare effects on consumers include those experienced by U.S. citizens and effects on consumers in the rest of the world (ROW), with the ROW effects being net of welfare changes for ROW producers. *Benefits* from pesticide regulation that arise outside the commodity market concerned (e.g., environmental benefits) are explicitly excluded from the LZ analysis, although pesticide regulation is aimed at providing such benefits.

In treating welfare impacts on foreign consumers identically to impacts on domestic consumers, LZ depart from the common practice of conducting cost-benefit analysis from a national perspective. It is of interest to ask whether the LZ results are changed if only welfare effects experienced in the

United States are counted. To help in answering this question, welfare effects of a pesticide ban that were summarized in table 2 in LZ are represented in a more disaggregated form in Table 1. The key step is the separation of changes in consumer welfare into U.S. and ROW components. This was done by taking foreigners' share in consumption of U.S. production of each commodity in the period 1980-1985 as the ROW's share in LZ's measures of consumer surplus. The ROW's shares were: corn, 26 percent; cotton, 45 percent; and rice, 51 percent (Economic Research Service, 1987). Applying these percentages to LZ's estimates of welfare losses to *world* consumers (column 2) from pesticide regulation gives welfare changes to ROW consumers as shown in column 6.¹ This simple exercise in disaggregation results in several important changes in the LZ results.

¹The elasticities of demand used by LZ in calculating welfare effects on world consumers were weighted averages of elasticities of U.S. and ROW (excess) demand. Our approach to calculating the change in ROW consumer surplus implicitly assumes that the elasticities for the two components of demand are identical. This may seem to be inconsistent with the reality that export elasticities of demand are typically much larger than domestic ones. However, simulations reveal that the size of the change in world consumer surplus and its distribution between U.S. and foreign consumers is insensitive to changes in the relationship between U.S. and ROW elasticities of demand. For corn, for example, using the weighted average elasticity of demand of -0.5 employed by LZ, the ROW share of the fall in world consumer surplus from U.S. pesticide regulations was approximately 26.0 percent when the U.S. and ROW elasticities of demand were assumed to be equal, and approximately 25.8 percent when the ROW elasticity was assumed to be 20 times as large as the U.S. elasticity. Of course, if stronger supply responses in ROW meant that the weighted average elasticities of demand for U.S. commodities were higher in the long run than the elasticities used by LZ, the ROW's share of consumer losses from U.S. pesticide regulation would fall as the United States lost export markets.

*School of Agriculture, La Trobe University, Melbourne, Australia 3083, and Department of Economics, La Trobe University, respectively. We acknowledge helpful comments by A. Myrick Freeman and an anonymous reviewer.

TABLE 1—WELFARE EFFECTS OF PESTICIDE REGULATION WITH A TARGET PRICE

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
				ΔCS (WORLD)					
Commodity	ΔW (WORLD)	ΔCS (WORLD)	ΔGP (U.S.)	$-\Delta GP$ (U.S.) (2-3)	ΔPS (U.S.)	ΔCS (ROW)	ΔCS (U.S.)	$\Delta(CS - GP)$ (U.S.) (7-3)	ΔW (U.S.) (1-6)
Corn	-43	-120	-131	12	-55	-31	-89	42	-12
Cotton	-20	-88	-99	12	-32	-40	-48	51	20
Rice	-5	-25	-28	3	-8	-13	-12	16	8

Notes: ΔCS , ΔPS , ΔGP , and ΔW denote changes in consumers' surplus, producers' surplus, government payments and net welfare, respectively. All table entries are in units of \$ million.

Source: Entries in columns 1-5 are from LZ. Entries in columns 6-9 were calculated by the authors.

First, accepting LZ's estimates of welfare losses to world consumers (column 2) from pesticide regulation with a target price, losses to U.S. consumers (column 7) ranged from just under half of world consumer losses for rice to about three-quarters of world consumer losses for corn. Second, for U.S. taxpayers cum consumers, the gains (see column 8) are from $3\frac{1}{2}$ to 5 times those obtained by LZ (see column 4) for consumers (world) cum taxpayers (U.S.). Third, aggregate welfare changes for the United States with a target price (column 9) are much more favorable than the welfare changes presented by LZ for the world market (column 1). For corn, the U.S. welfare loss is less than one-third that found by LZ for the world corn market. For cotton and rice, the changes are even more dramatic: world welfare losses of \$20 million and \$5 million become welfare gains of \$20 million and \$8 million, respectively, to the United States.

It is the *domestic* welfare effects of pesticide regulation, not the global effects, that are likely to be most relevant to the U.S. debate on pesticide regulation. Disaggregation of the LZ analysis shows that, in the presence of price supports, pesticide regulation in the United States is much more attractive from a domestic perspective than from a global perspective. This point may be reinforced if (domestic) nonmarket benefits, such as environmental improvement, were incorporated.

Independent Auditors' Report

Executive Committee
The American Economic Association
Nashville, Tennessee

We have audited the accompanying balance sheets of The American Economic Association as of December 31, 1990 and 1989, and the related statements of revenues and expenses, changes in general fund and restricted fund balances and cash flows for the years then ended. These financial statements are the responsibility of the Association's management. Our responsibility is to express an opinion on these financial statements based on our audits.

We conducted our audits in accordance with generally accepted auditing standards. Those standards require that we plan and perform the audit to obtain reasonable assurance about whether the financial statements are free of material misstatement. An audit includes examining, on a test basis, evidence supporting the amounts and disclosures in the financial statements. An audit also includes assessing the accounting principles used and significant estimates made by management, as well as evaluating the overall financial statement presentation. We believe that our audits provide a reasonable basis for our opinion.

In our opinion, the financial statements referred to above present fairly, in all material respects, the financial position of The American Economic Association as of December 31, 1990 and 1989, and the results of its operations and its cash flows for the years then ended, in conformity with generally accepted accounting principles.

A handwritten signature in cursive script that reads "Deloitte & Touche".

	<u>\$ —</u>	<u>—</u>

See notes to financial statements.

The American Economic Association Notes to Financial Statements for the Years Ended December 31, 1990 and 1989

1. Summary of Significant Accounting Policies

Investments are accounted for on a market-value basis. The investment income recognized is modified to reflect only the Association's approximate historical average rate of return, which is currently 5 percent. Investment income represents 5 percent of the total cash and market value of investments at the beginning of the year. The change in market value of investments and dividends and interest earned net of investment income recognized is recorded directly to the general fund.

Accrual for Survey of Members. Every three to five years, the Association publishes a survey which lists, among other things, the names and addresses of its membership. This survey was most recently published in 1989 and distributed at no cost to the membership. In order to properly match the publishing cost of this survey with revenue from membership dues, the Association provided \$70,000 in 1990 and 1989 for estimated publishing costs which will reduce actual survey expenses in the year of publication.

Deferred revenue represents income from membership dues and subscriptions to the various periodicals of the Association which are deferred when received. These amounts are then recognized as income following the distribution of the specified publications to the members and subscribers of the Association. Income from life membership dues is recognized over the estimated average life of these members.

The American Economic Association files its federal income tax return as an educational organization, substantially exempt from income tax under Section 501(c)(3) of the Internal Revenue Code. As required by Section 511(a) of this Code, the Association provides for federal income taxes on certain revenues which are not substantially related to its tax-exempt purpose. This "unrelated business income" includes income from advertising and the sale of mailing lists. The Association has been determined to be an organization which is not a private foundation.

Certain restricted funds are administered on a reimbursement basis; therefore, disbursements are allowed prior to receipt of grant proceeds.

Certain reclassifications have been made to the 1989 amounts in order to conform to the 1990 presentation.

2. Investments and Investment Income

Investments consist of:

	December 31, 1990		December 31, 1989	
	Cost	Market	Cost	Market
Government obligations, bonds and commercial paper	\$ 627,144	\$ 645,520	\$ 586,999	\$ 617,179
Mutual funds	<u>4,170,729</u>	<u>4,336,752</u>	<u>4,578,432</u>	<u>5,138,890</u>
	<u>\$4,797,873</u>	<u>\$4,982,272</u>	<u>\$5,165,431</u>	<u>\$5,756,069</u>

Investment income recognized consists of:

	Year Ended December 31	
	1990	1989
Government obligations, bonds and commercial paper—interest	\$ 70,436	\$ 92,817
Corporate stocks and mutual funds—cash dividends	300,557	471,922
Corporate stocks and mutual funds—net gain (loss) on sale	(94,663)	11,094
Change in market value	(406,239)	548,707
Transfer to general fund, net	<u>450,212</u>	<u>(827,486)</u>
Investment income recognized, net	<u>\$320,303</u>	<u>\$297,054</u>

3. Retirement Annuity Plan

Employees of the Association are eligible for participation in a contributory retirement annuity plan. Payments by the Association and participating employees are based on the employee's compensation. Benefit payments are based on the amounts accumulated from such contributions. The total pension expense was approximately \$50,000 and \$42,000 for 1990 and 1989, respectively.

4. Ratio of Net Worth to Expenses

The ratio of net worth at December 31, 1990 to 1991 budgeted expenses is 1.24 and the ratio of net worth at December 31, 1989 to actual 1990 expenses is 1.47.

Begin making plans to attend the

Annual Meeting of The American Economic Association

(in Conjunction with Allied Social Science Associations)
to be held in

NEW ORLEANS, LA

Jan. 3-5, 1992

The Employment Center opens Thursday, January 2; sessions begin Friday, January 3.

See the September *AER* for the American Economic Association's preliminary program.

The 1993 meeting will be held in Anaheim, CA, January 5-7, 1993.

The Governmental Habit Redux **Economic Controls from Colonial Times to the Present**

Jonathan R. T. Hughes

To the distinguished economic historian Jonathan Hughes, the ambiguous outcomes of attempted deregulation signal America's urgent need to probe the origins of our vast and chaotic maze of government economic controls. Why do government restrictions on the economy continue to proliferate, in spite of avowed efforts to allow the market a freer rein? How did this complicated network of nonmarket economic controls come about and whose purposes does it serve? While exploring these questions, Hughes updates his classic book *The Governmental Habit* to reflect the experience of what he calls the "wild ride" of the last fifteen years.

"Jonathan Hughes is probably the only living economic historian with the breadth of vision and open-mindedness to produce a book like this."—Hugh Rockoff

Cloth: \$29.95 ISBN 0-691-04272-1

The Business Cycle **Growth and Crisis under Capitalism**

Howard J. Sherman

Are the recurring recessions of the capitalist world merely short-term adjustments to changing economic circumstances in a system that tends, in general, toward equilibrium? In this accessible study of the business cycle, Howard Sherman makes a powerful case that recessions and painful involuntary unemployment are endogenous to capitalism. Drawing especially on the work of Wesley Clair Mitchell, Karl Marx, and John M. Keynes, Sherman explains why the nature of the business cycle produces serious economic loss and misery during its contraction phase, just as it produces growth in its expansion phase. For anyone interested in how the U.S. economy operates, this book will be an invaluable resource.

"This book will not only contribute to the existing literature on business cycles but will also become a standard reference for all students and researchers in the field."—Martin H. Wolfson

Cloth: \$45.00 ISBN 0-691-04262-4

The World Trading System at Risk

Jagdish Bhagwati

Jagdish Bhagwati, one of the world's leading economists, offers a fascinating overview of the perils and promise facing the world trading system. He refutes facile but fashionable criticisms of the General Agreement on Tariffs and Trade (GATT). Warning of the dangers of flouting the GATT's provisions, he shows that its underlying conception of trading by rules will be undermined if the U.S. extends accusations of "unfair trade" practices to areas as diverse as retail distribution systems, infrastructure spending, saving rates, and workers' rights.

"... a thoughtful, scholarly, and authoritative analysis of the current status and future potential of GATT."—Milton Friedman

Cloth: \$16.95 ISBN 0-691-04284-5

Not available from Princeton in the United Kingdom and Europe

Efficiency Wages

Models of Unemployment, Layoffs, and Wage Dispersion

Andrew Weiss

Known for his seminal work in efficiency-wage theory, Andrew Weiss surveys recent research in the field and presents new results. He shows how wage schedules affect the kinds of workers a firm employs and how well those workers perform on the job. Using straightforward examples, he demonstrates how efficiency-wage theory can explain labor market outcomes and guide government policy. There is a separate section of applications to less developed countries.

"Efficiency Wages should be on the bookshelf of all labor and macroeconomists."

—Lawrence H. Summers, *Harvard University*

Paper: \$8.95 ISBN 0-691-00388-2 Cloth: \$29.50 ISBN 0-691-04279-9

Essays on the Intellectual History of Economics

Jacob Viner

Edited by Douglas A. Irwin

Ranking among the most distinguished economists and scholars of his generation, Jacob Viner is best remembered for his work in international economics and in the history of economic thought. Never before, however, have Viner's important contributions to the intellectual history of economics been collected into one convenient volume.

"Jacob Viner was a great and original economic theorist. What is rarer, Viner was a learned scholar. What is still rarer, Viner was a wise scientist. This new anthology of his writings on intellectual history is worth having in every economist's library—to sample at intervals over the years in the reasoned hope that Viner's wisdom will rub off on the reader and for the pleasure of his writing."—Paul A. Samuelson

Crisis amid Plenty

The Politics of Soviet Energy under Brezhnev and Gorbachev

Thane Gustafson

Although the Soviet Union has the most abundant energy reserves of any country, energy policy has been the single most disruptive factor in its industry since the mid-1970s. This major case study treats the paradox of the energy crisis as an essential part of larger economic problems of the Soviet Union and as a key issue in determining the fate of the Gorbachev reforms.

"... should interest Soviet specialists, in both universities and government, and prove instructive for students of the Soviet economic system, graduate or undergraduate."—Choice

ANNOUNCING

TSP VERSION 4.2

Enhancements in
Version 4.2 include:

NEW TIME SERIES PROCEDURES

- Vector autoregressions
- Kalman filter estimation
- Shiller lags
- GARCH-M estimation
- Dickey-Fuller distribution for testing

OTHER NEW FEATURES

- Panel data estimation
- GMM estimation
- Matrix algebra with easy expressions like $(X'X)^{-1}X'Y$

... and much more.

**Now the oldest econometric software
package is better than ever.**

If you have a DEC Vax, IBM mainframe, PC/286/386 or compatible, or Unix workstation, then we have a copy of Version 4.2 for you.

**ALSO AVAILABLE NOW:
TSP VERSION 4.1B FOR MACINTOSH**

Announcing a New Firm Specializing in Finance

Kolb Publishing Company

Understanding Futures Markets (3rd Edition)—Robert W. Kolb

The third edition of this leading text maintains the high readability and teachability of the first two editions. The new edition extends the coverage of financial futures and includes many more examples. It has the most up-to-date coverage of hot topics such as Globex, the accelerating internationalization of the markets, and the continuing struggle between the CFTC and the SEC. Now with an instructor's manual. Available January 2, 1991.

Options: An Introduction—Robert W. Kolb

This completely new text provides a comprehensive introduction to options. After discussing the market environment, the text analyzes option values at expiration and the no-arbitrage bounds on option prices before expiration. A thorough discussion of the Binomial Model provides a stepping stone to the Black-Scholes Model. The book also covers currency options, stock index options, and options on futures. Included with the text is **OPTION!** software. With **OPTION!**, students can analyze and graph profits and losses for option combinations; analyze binomial option values with multiple periods; find Black-Scholes option values; approximate Black-Scholes values with the binomial model; and simulate stock and option price paths. The software is fully integrated into the text to provide a comprehensive teaching package. Instructor's manual. Available now.

The International Finance Reader—edited by Robert W. Kolb

This text provides the most timely, comprehensive, and readable selection of articles on international finance. The text includes a mix of enduring classics and the best articles on recent trends in global finance and banking. It includes coverage of the Japanese financial markets, the debt crisis of the developing countries, and the international financial implications of Eastern Europe's emergence from Communism. Available now.

Financial Institutions and Markets: A Reader—edited by Robert W. Kolb

By focusing on current and readable articles, this text stays apace of the continuing financial revolution in the United States and abroad. Designed as a course supplement, the text contains very recent and highly readable articles to bring the real world into the classroom. Topics include: the savings and loan crisis, the changing face of U.S. financial regulation, new financial instruments, the interaction of stocks, futures and options, the junk bond market, and innovations in the management of financial institution. Available now.

Please mention THE AMERICAN ECONOMIC REVIEW When Writing to Advertisers

QUESTION: Where is the "best" place to reach over 15,000 professionals who need your expert services?

ANSWER: The Expert Services Section of **Best's Directory of Recommended Insurance Attorneys!** Since 1928, we have addressed the needs of insurance defense attorneys and other legal/claims officers by providing this "one-of-a-kind" publication.

Our **Expert Services Section** identifies professionals providing assistance to the insurance and legal defense industries. Each firm listing contains information on services rendered, membership affiliations and firm members. Here are just some of the services represented in this section:

- Independent Shorthand Reporters
- Special Investigators
- Structured Settlement Firms
- Testing Laboratories
- Handwriting Experts

- Engineering Experts
- Environmental Specialists
- Meteorologists
- Rehabilitation
- Construction Consultants
- Economic Consultants
- Consultants

Having your firm included in this publication is truly a mark of distinction. For over 90 years, **A.M. Best** publications have been regarded as *authoritative, reliable and accurate*, because we always verify our information before releasing it to the public.

A listing in this Directory begins by filing a "Confidential Firm Report." Each individual or firm that applies for a listing is required to provide a list of clients for verification and recommendation. Upon acceptance of these credentials, a nominal fee will be charged to be listed in this prestigious publication.

Don't miss this exciting opportunity — **ACT NOW** by completing the attached coupon and mail, or fax the information to (908) 439-3296 to begin the selection process. Please respond immediately, as we need this information *no later than August 1, 1991*.

PUBLIC GOODS, MIXED GOODS, AND MONOPOLISTIC COMPETITION

Stephen Shmanske

IN THIS BOOK, Stephen Shmanske builds a theoretical bridge between public goods and monopolistic competition, suggesting that they are different dimensional simplifications of the same general model. His conclusions have great relevance to policy formation on public goods provision.

Shmanske argues that public goods models have usually ignored or simplified the utilization dimension. Furthermore, private goods models in the monopolistic competition vein have two implicit dimensions of consumption, but again, one is treated in a very constrained fashion. The general, mixed goods model draws from both traditions, using the results of one model to generalize and extend the other. 200 pp. 9 b&w illus. Bib. Index. \$45.00s

A History of Interest Rates

Sidney Homer and Richard Sylla

New Third Edition

With a foreword by Henry Kaufman

Sylla has revised and updated this third edition, which now carries the history of interest rates to 1989. Highlights of the new edition include documentation of the recent ascent of interest rates throughout the world to their highest levels since the Middle Ages, a great deal of

new information on Japan and the European Economic Community, more information on real interest rates and consumer interest rates, expanded treatment of the United States, and updated charts and tables.

GENERAL EQUILIBRIUM MODELS FOR MICRO-COMPUTERS

GEMODEL.USA

A large-scale general equilibrium model of the U.S. economy.

The package is completely menu-driven and accomplishes every job from data entry through consistency checks, calibration and policy changes to solution and report printing.

The model can be used to analyze the effects of changes in tax policy, product demands, technology, productivity etc. on incomes, outputs, tax revenue and foreign trade.

PRICES:

Academic Version	US\$ 2,200
Professional Version	US\$ 8,100

GEMODEL.USA is for policy analysis and research in government, university and industry.

A special purpose of the model is to simulate value-added taxes and the separate tax policies of two levels of government:
Federal
State/Local

GEMODEL.USA has a phenomenal number-crunching capability. It accepts the 85-industry, U.S. input-output tables prior to aggregation of industries, consumption categories, and households. The level of detail carried by the model is larger than that commonly found in the general equilibrium literature.

The package is easy to run and is perhaps the only software that produces simulation results on your own desk within seconds. It is available in two versions: Professional and Academic.

The Professional version allows greater disaggregation and the computation of dynamically sequenced equilibria.

Both models are supplied with sample data that can be edited or replaced with your own or another country's data.

SYSTEM REQUIREMENTS: IBM-PC or compatible, 384K RAM, 1 drive, DOS 2.1 or better.

Available on 5¼ and 3½ inch diskettes.

GEMODEL 2.0

Solves open or closed, two or three-industry small open economy models employing two or three factors. Industries can have constant or diminishing returns to scale. Admits one to nineteen household groups with or without income/leisure choice. Solves with a wide array of factor, commodity and income taxes.

"GEMODEL is a powerful microeconomic simulation model."

"I highly recommend it for both instructional and research purposes." *Social Science Micro Computer Review*, 1987.

"This package opens up exciting possibilities for students to explore and verify economic theory..." *Economic Journal*, 1990.

PRICE: US\$ 395.00

GESTATS

Calibrates GEMODEL 2.0 parameters to data and elasticity assumptions. Checks data consistency.

PRICE: US\$ 195.00

GEREPORT

Compares GEMODEL 2.0 simulation results with the base case or with other simulation results. Computes measures of welfare change and marginal costs of taxes.

PRICE: US\$ 95.00

GEDATA

24 data files for exercises in price theory, trade and finance using GEMODEL 2.0

PRICE: US\$ 25.00

Economic Policy Alternatives for the Latin American Crisis

Joan B. Anderson, Department of Economics,
University of San Diego, CA

This book explores macroeconomic policy alternatives available to Latin American policy-makers from both a theoretical and empirical perspective. It presents a quantitative framework in which to evaluate the effectiveness of various types of monetary and fiscal policies under the current conditions of inflation, declining growth, and debt.

The International Debt Crisis

Debt Equity Conversion - A Guide for Decision Makers

- *definition of policy objectives*
- *analysis and clarification of instrumentalities*
- *examination of national experiences through case studies*
- *assessment of creditor country constraints*

Debt Equity

CONVERSION

A Guide for
Decision-makers

In 1984-1989 alone, debt equity conversions amounted to \$22 billion. As substantial as this is, this new study concludes that these conversions have had limited impact on debt reduction and the creation of new investment. This thorough examination of a complex topic provides decision makers with the tools to define their options and take appropriate action in the area of debt equity conversion. This book reviews the basics of the debt equity concept, its history, and typical deals and examines the role of all the parties involved in conversions as well as the benefits to debtor countries and constraints on creditor countries. Notably, this guide offers a detailed checklist of issues that any country considering a debt equity conversion programme is obliged to confront. This study pays particular attention to the experiences of Mexico, Brazil, Chile, Argentina, the Philippines and Jamaica.

E.90.II.A.22 92-1-104352-2 \$27.50

Transnational Banks and the International Debt Crisis

Very little attention in this crisis is paid to the role of transnational banks (TNBs) even though a large part of the developing countries' debt is owed to them. This book analyses how TNBs contributed to the creation of the international debt problem by providing excessive loans in defiance of normal prudential criteria and how their subsequent activities have helped prolong the problem.

ySTAT / yCHART / yMED™

Integrates

SPREADSHEET + STATISTICS + FORECASTING + GRAPHICS

For all models of IBM PC's and Macintosh Computers

- ySTAT is the only full-fledged spreadsheet statistical program - a fast, powerful, easy-to-use stand-alone program.
- Menu-driven format as in Lotus 1-2-3 - offers many functions that are not available even in 1-2-3, such as vector formulas, lagged variables, dummy variables, moving averages, and interpolation of missing values.
- You can read, enter, edit, copy, move, and sort the data as well as group and partition the data for analysis right on the spreadsheet. A total of 40 function keys for one-keystroke operations.
- ySTAT reads 1-2-3 and Symphony worksheet files directly, and any tree-format or fixed-format textfile generated by other PC programs or downloaded from mainframe. The data can be numeric, alphabetic, including missing values.
- Mean, median, quartiles, skewness, mode, t-test, frequency distribution, correlation, crosstabs, analysis of variance.
- Multiple regression (OLS), standardized regression, weighted least squares, two-stage least squares, polynomial regression, and Cochran-Orcutt method. Including diagnostic residual analysis output (see sample at right).
- Pooling of cross-section and time-series data.
- Two-sample difference of means test, nonparametric tests (Kolmogorov-Smirnov test, Wald-Wolfowitz runs test, Mann-Whitney test, Wilcoxon matched-pairs signed-ranks test) and Spearman's and Kendall's rank-order correlations.
- Time-series models: autoregressive model, moving average model, and Box-Jenkins model (ARIMA).
- Nonseasonal forecasts: linear trend, quadratic trend, polynomial model, sinusoidal model; simple, double and triple exponential smoothings.
- Seasonal forecasts: exponential smoothings with seasonal indicators or with trigonometric functions; Winters' additive and multiplicative procedures.
- Logit, Probit, Tobit, and Weighted Probit regressions: these models are fast and easy to use.
- Will automatically use expanded memory (EMM) if available.
- High-resolution color charts: the actual and forecast values are graphically displayed as a line chart and also as an XY chart, including a regression line and its 95% confidence interval.

Crude Oil Futures Prices - High, Low, Close & Open Interest

- yCHART offers multiple charts in one window. There are line, XY, bar, stacked-bar, area, high-low-close-volume, pie, and survival charts. The Macintosh version has the addition of horizontal bar, histogram, box, moving average/oscillator, and spread charts.
- yMED is a medical version of ySTAT. It has, among others, Mantel-Haenszel odds ratio, risk difference and ratio, incidence rate difference and ratio; loglinear model; Kaplan-Meier survival model.
- APPLE MACINTOSH VERSION**
The Mac version builds on the features of the IBM PC version and extends the worksheet to three dimensional - there can be a maximum of 24 worksheets in a multiple-window environment. Each worksheet represents a separate data set; you can perform same or different statistical procedures on different worksheets displayed simultaneously on the screen. A series of worksheets can also be combined in several ways - appended, merged, combined (summed up). You can also copy, cut, move, and paste between worksheets to exchange data. The Mac yCHART offers many chart types for commodity futures trading.

IBM is a registered trademark of International Business Machines Corp.; Macintosh of Apple Computer, Inc.; 1-2-3 of Lotus Development Corp.

Informative Additions to Economic Knowledge.

Economic Analysis of Industrial Policy

Motoshige Itoh, Kazuharu Kiyono,
Mashahiro Okuno-Fujiwara, and
Kotaro Suzumura

*A Volume in the ECONOMIC THEORY,
ECONOMETRICS, AND MATHEMATICAL
ECONOMICS Series (edited by Karl Shell)*

Written by four prominent Japanese economists, this book is a preliminary step for building a general theoretical framework for analyzing industrial policies. It achieves this goal by analyzing industrial policies in terms of economic theory, discussing the various frameworks suitable for evaluating these industrial policies in an objective manner, and by determining which policy measures are appropriate if an industrial policy is to be implemented.

Key Features:

- Discusses a general framework for adopting industrial policy from the perspective of post-war Japanese economists
- Discusses problems facing developing countries, especially the newly industrializing countries, that adopt Japan's strategies
- Provides a theoretical analysis of Japanese industrial policies and their effect on economic welfare, taking into consideration their distinctive features

CONTENTS: (Section heads)

Industrial Promotion and Trade. Oligopolistic Control of an International Market. Welfare Implications of Strategic Competition in Oligopolistic Industries. Research and Development Investment. Further Problems in Formulation of Future Industrial Policy. References. Index.

June 1991, c. 280 pp., \$74.95 (tentative)
ISBN: 0-12-375735-5

Game Theory and Applications

edited by

Tatsuro Ichiishi,
Abraham Neyman,
and Yair Tauman

*A Volume in the ECONOMIC THEORY,
ECONOMETRICS, AND MATHEMATICAL
ECONOMICS Series (edited by Karl Shell)*

Key Features:

- Highlights new research directions in economic theory which surpass the neoclassical paradigm
- Includes game-theoretical analyses in economics, political science, and biology
- Written by leading game theorists, economists, political scientists, and biologists

December 1990, 436 pp., \$89.95

The International Financial Regime

edited by

Graham Bird

*A Volume in the SURREY SEMINARS
IN ECONOMICS Series*

A Co-publication with Surrey University Press

International Financial Regime

addresses the central questions of international finance and economics in a lively and readable style. The contributors are all acknowledged experts in their fields and each contribution presents an accessible survey of the often complex issues which make up the international monetary system. This book is a useful reference for economists, policy makers, and advanced students of international economics.

1990, 360 pp., \$75.00

ISBN: 0-12-099745-2

Trade, Policy, and International Adjustments

edited by

Akira Takayama,
Michihiro Ohyama,
and Hiroshi Ohta

*A Volume in the ECONOMIC THEORY,
ECONOMETRICS, AND MATHEMATICAL
ECONOMICS Series (edited by Karl Shell)*

Key Features:

- Examines recent issues in the theory of international trade and its application to commercial policies, such as voluntary export restrictions, trade versus aid, and multinational corporations
- Analyzes macroeconomic issues such as exchange rates, monetary economies, and tariffs and quotas
- Extends trade theory to investigate the implications of variable returns to scale, intermediate inputs, and the question of choice between free and controlled trade

February 1991, 305 pp., \$45.00

ISBN: 0-12-682230-1

INDEX OF ECONOMIC ARTICLES

prepared by

The Journal of Economic Literature
of the
American Economic Association

- ✓ Each volume in the **Index** lists articles in major economic journals and in collective volumes published during a specific year.
- ✓ No other single reference source covers as many articles classified in economic categories as the **Index**.

Index volumes XI-XXII covering 1969-1980 are available at \$60.00 each.

The following two part **Index** volumes are now ready for delivery at \$90.00 per set:

Volume	Year
XXIII	1981
XXIV	1982
XXV	1983
XXVI	1984
XXVII	1985
XXVIII	1986
XXIX	1987
